NOTE ON ACTION OF TESTICULAR EXTRACT.

By Allen J. Smith, M.D.,
Professor of Pathology, University of Pennsylvania.

And W. J. Crocker, V. M. D.,
Instructor in Veterinary Pathology, University of Pennsylvania.

From the McManes Pathological Laboratory of the University of Pennsylvania.

As a part of a series of investigations having as their ultimate purpose the production of tumors, the writers conducted a group of experiments in the summer and fall of 1910, with observation for a period of twelve months thereafter, upon the combs of old hens subjected to frequent injection of a salt solution extract of the testicles of cocks. The underlying hypothesis tentatively assumed that in the development of neoplasms three factors are combined: (a) That the cells from which tumors grow should be afforded a full pabulum for growth (other things being equal, should be in a part well supplied with blood circulation); (b) that such cells should be more or less independent in their structural relations (cut off from their proper relations as congenital "rests" or disturbed in relation by injury and imperfect repair); and (c) should be subjected to a stimulus to growth (such stimulus perhaps of external origin, or perhaps of internal origin as quantitative faults of internal secretions or faulty metabolites retained in the system). The comb of the hen was chosen because of its exposure to ready observation and manipulation, and because it is a part usually well vascularized and therefore well nourished; and because of its commonly observed variations in different times in the life of the hen it was supposed to be a part easily influenced by stimuli or by depressants to growth. Moreover, several years previously Walker (Proceedings, Royal Medical Society, Liverpool, April, 1908, i, No. 6, pp. 153-156) in studying the development of secondary sexual characteristics in fowls had pointed out among other features the enlargement of the combs of hens injected frequently with a salt solution of cock's testicle. By a variety of means it was sought to establish the second hypothetical factor, that of disturbance of cellular structural relations, in the hens subjected to experimentation, these including such measures as producing inflammations of the comb by repeated puncture, scratching, introduction of various foreign particles, introversion of the superficial tissue, attempts to establish long continued but mild electric intrahistological currents, etc. Coincidentally a salt solution extract of cock's testis was injected subcutaneously at a distance from the comb, usually under one or other wing, at first daily, toward the latter part of the period of injection every third or every fourth day. The extract of testis was made of a ten per cent. strength of fresh sterile testis in normal salt solution. A fresh testis having been obtained and weighed, it was with due precautions cut into fine bits, and in a small amount of normal saline was well ground in a mortar with coarsely powdered sterile glass, sufficient normal salt solution being thereafter added to bring the total amount of the solution used to ten times the weight of the testis. This was then placed in a sterile protected flask in the refrigeration for twenty-four hours, and thereafter passed through a tested sterile Berkefeld filter; and the filtered extract distributed in sterile vials. These vials were placed for forty-eight hours in the incubator and those showing growth of bacteria were rejected. At the same time tubes of ordinary media were inoculated with the filtered extract from each vial, and in case of positive growth the vial in question was rejected.

It is almost needless to state that the attempts to produce tumors of any sort failed. The injections were continued from the early part of July until well into October (a period of three months), and the hens were kept under observation for a full year longer before they were discarded. If the original hypothesis be correct, the writers are disposed to attribute failure to a lack of success in providing sufficiently well the second factor named, that of inducing deviations of cellular relations in the comb (i.e., of producing artificial "rests" of cells capable of responding to the stimulus of the testicular extract); for unquestionably the first of the three factors, that of the existence of suitable blood supply, existed in the site of manipulation; and the third, that of induction of growth of the comb, was clearly successful, as evidenced by the following statements and illustrations. Until some more certain method of producing disturbance of cellular relations is at hand, the writers have postponed further prosecution of this line of study, but feel that in confirmation of Walker's studies it may be of interest to record by publication the effect of the testicular extract upon the growth of the comb in hens.

Twelve hens were obtained June 21, 1910, in the market, all mature, certainly none of less than a
full year of age, and from their appearance all probably three or four years old. Tracings of the outline of the combs were made the same day, or on the day of beginning injection (line 1 in each of the diagrams); and general descriptions of each hen with particular description of the comb of each recorded. Thereafter until July 6, 1910, the hens were allowed to become accustomed to their house and yard and were well fed. During this period, after the first day or two, from three to five eggs were collected daily until some time after the injections were begun; and the hens thrived. On July 6th, injections of 2.5 c.c. of testicular extract were started, and continued daily until September 30th, after which the injections were made at intervals of several days; and were finally discontinued on October 25th. During the same period the local irritation of the combs was performed at intervals of about one week. The combs were traced in outline on July 10th (line 2 in diagrams), on August 3rd (line 3 in diagrams), and on November 23rd (line 4 in diagrams), the last about a month after the last injection. It should be stated that in October several severe frosts occurred, as well as in November. It was intended to measure the combs at about the same time that injections of extract were discontinued; but just before this time a cold period occurred in which a distinct shrinkage of the combs took place, and measurement was postponed with the hope that with a succeeding warm period there would follow restoration. This did not occur, and the final measurement shows in almost all the hens a decrease, which in part is surely due to the cold weather to which the fowls were exposed in their yard and coop built of a well roofed piano box and kept out of doors; in part it is probably due to the suspension of the testicular extract and to intercurrent diseases of the hens, but might well be disregarded so far as the influence of the testicular material is concerned because of the confusion unquestionably depending upon these other factors.

In a general way, with few exceptions, Walker's statements were well supported by our own results. The combs of most of the hens actually increased in size, both in the flat outline, as shown in the diagrams, and also in thickness, not shown in the tracings. The combs brightened; the wattles in correspondence enlarged and brightened; in some of the hens the neck feathers became somewhat more brilliant; and slight growth and brilliancy of color appeared in the small feathers at base of tail; in one a slight but distinct growth in spurs was recognized; the production of eggs diminished, and ceased after August 24th; some of the hens became combative, and several times individuals were seen to attempt to cover other hens after the manner of the cock. It would perhaps have been well to perform control experiments by injecting ovarian extracts in the same way into hens and cocks; but this was not done, since the direct purpose of the work was not concerned with the broader biological fact. However, as far as the observations go, they are suggestive of the credibility of the idea that upon some internal secretion from the testis, a hormone, the prominent secondary sex characteristics of the male bird are dependent; and are here presented merely for their "face value" and no more.

The variations in the size of the combs are sufficiently indicated by the outline tracings of each, and are submitted without further general comment:

**Hen 1:** Comb on June 21, 1910, pale and dingy red in color; measurement, line 1. Comb on July 10, 1910, unchanged. Comb on August 2, 1910, unchanged. Comb on November 23, 1910, unchanged. (Fig. 1.)

**Hen 2:** Comb on June 21, 1910, bright red; measurement, line 1. Comb on July 10, 1910, unchanged. Hen combative, feathers of neck and base of tail becoming metallic green. Comb on August 2, 1910, measurement, line 3. Hen died in early part of November, with marked...
fluid exudate in peritoneum. Had had a local infection under wing in region of injections; and this and exposure believed to have caused death. The hen had in the course of the injections manifested marked male characters in combativeness and attempting to cover other hens. (Fig. 2.)

Hen 5: Comb on July 6, 1910, bright red, large, measurement, line 1. Comb on July 19, 1910, measurement, line 2; small papillary growths near base of comb; hen struts, combative. Comb on August 2, 1910, measurement, line 3; hen continues to show male tendencies. Comb on November 23, 1910, measurement, line 4. (Fig. 3.)

Hen 4: Comb on July 6, 1910, large, bright red; measurement, line 1. Comb on July 19, 1910, measurement, line 2; wing, neck, and tail feathers coarse and glossy. Comb on August 2, 1910, no change. Comb on November 23, 1910, unchanged, line 4. (Fig. 4.)

Hen 5: Comb on June 21, 1910, small, pale; measurement, line 1. Comb on July 19, 1910, no change. Hen sick and droopy. Comb on August 2, 1910, no change. Has been sick until last day or two. Comb on November 23, 1910, measurement, line 4. Increased. Wartlike growth appeared on comb but disappeared (August 12th to September 24th). (Fig. 5.)

Hen 6: Comb on July 6, 1910, large, dirty red; measurement, line 1. Comb on July 19, 1910, increased, measurement, line 2; tail feathers coarse, showing growth. Comb on August 3, 1910, shrunk, line 3; a fungous disease spreading from base of comb appeared first on July 29th, with loss of color and constant shrinkage. Comb on November 23, 1910, shrunk, line 4. A new spur, one half inch long, had grown, tail large. On September 8th a white false membrane appeared in mouth and throat, treated with mercuric chloride swabs for a week, when the parts appeared and remained normal. (Fig. 6.)

Hen 7: Comb on June 21, 1910, small, bright red; measurement, line 1. Comb on July 10, 1910, no change in size but with many fine papillary outgrowths upon it. Neck and tail plumage brighter. Comb on August 3, 1910, slight increase; line 3. Comb on November 23, 1910, shrunk. line 4. (Fig. 7.)

Hen 8: Comb on July 6, 1910, small, good red color; measurement, line 1. Comb on July 19, 1910, increased; line 2; neck and tail feathers coarser and brighter. Comb on August 2, 1910, increased; line 3. Comb on November 23, 1910, shrunk, line 4. (Fig. 8.)

Hen 9: Comb on July 6, 1910, large, good red color; measurement, line 1. Comb on July 19, 1910, increased; line 2; neck and tail feathers larger; feathers on legs and feet growing. Comb on August 2, 1910, increased, line 3.

Hen died August 10, 1910, from a coccus infection at site of injection under wing. (Fig. 9.)

Hen 10: Comb on June 21, 1910, large, good red color; measurement, line 1. Comb on July 19, 1910, no increase. Hen combative. Infection at site of injection. Right eye swollen. Comb on August 2, 1910, no increase; infection in breast gone; eye still swollen. Comb on November 23, 1910, shrunk; line 4. (Fig. 10.)

Hen 11: Comb on June 21, 1910, small, not well colored; measurement, line 1. Hen sick from time of injection, and died July 15, 1910, from a pleuroperitonitis; no change in size of comb. (Fig. 11.)

Hen 12: Comb on July 6, 1910, large, good red color; measurement, line 1. Comb on July 19, 1910, increased; line 2. Comb on August 3, 1910, no increase; hen sick and droopy from July 24th until August 4th. From August 24th to August 25th fungous growths appeared on comb: dropped off between September 16th and September 23rd. Comb on November 23, 1910, shrunk, line 4. (Fig. 12.)

PLANS FOR THE REDUCTION OF INFANT MORTALITY.*

By Ernst J. Lederle, Ph.D.

President of the Board of Health, New York City.

The work of the Department of Health for the reduction of infant mortality will be conducted during the coming summer along lines which have been gradually developed and placed in full operation during the last few years. Before outlining these

*Read before the New York Academy of Medicine, May 25, 1913.
In 1876 the Department of Health, having recorded an unusually high mortality among infants, applied for and obtained a special appropriation for the employment of a staff of physicians during the months of July and August. These physicians were known as the "summer corps," and they were assigned to duty in the congested tenement house regions of the city, where they treated all sick babies whose parents were unable to obtain medical care. This plan was followed each summer for many years, and without doubt has been a contributing factor in the steady decreases in the number of infant deaths during the last thirty years. The effectiveness of the work was limited, however, because its purpose was restricted to the treatment of sick babies, rather than the prevention of illness.

In 1902 seventeen trained nurses were employed by the department, primarily for the work of school medical inspection. These nurses, however, assisted the physicians of the summer corps during the vacation months of July and August, and in house to house visits instructed mothers in the proper methods of preparing food for babies and demonstrated the correct principles of bathing, clothing, and airing. Thus the real preventive work of the department was begun in a small way.

With the establishment of a special Division of Child Hygiene in 1908, the summer work for babies became an important function of the new division. In May of that year the commissioner of health had organized a Conference on the Care of Babies in an effort to coordinate and make more effective the work of public and private agencies. This was the first definite effort to prevent duplication of such work, and the same idea is now carried out by the Babies' Welfare Association, organized in 1912.

The Division of Child Hygiene was formed in the autumn of 1908, and the appointment of a staff of 141 nurses made possible an important extension of the preventive activities of the department. Since that time the department has endeavored to visit mothers as soon as possible after the birth of the baby, and to provide continuous instruction in the effort to keep babies well, rather than rely on curing them after they have become ill.

It was now possible to undertake lectures on the care of babies each week at the various recreation piers, public playgrounds, and other social centres throughout the city. In cooperation with private agencies, the department assigned medical inspectors and nurses to the infants' milk stations conducted by the Brooklyn Children's Aid Society and the New York Diet Kitchen Association in 1909, 1910, 1911. Another idea which has been successfully developed and widely commented upon was the organizing of Little Mothers' Leagues among the girls attending the public schools.

In 1911 another important step was taken, in the establishment of municipal infants' milk stations. Successful as the work has been since 1908, it was still limited to a special campaign each summer, whereas the idea of the department was to treat infant mortality as an all the year round problem. An experimental appropriation for the establishment of fifteen infants' milk stations under the administration of the department, to be operated throughout the year, was an important step in this direction. The New York Milk Committee and other private agencies operated a much larger number of stations, and the result of the combined efforts was so encouraging in 1912 that the city authorities granted an additional appropriation for 1912 sufficient to increase the number of milk stations to fifty-five. The appropriations are so arranged as to permit of doubling the staff of attendants during the six months from May to November, but the stations are operated throughout the year, and the work of the department, along the lines which have been described, is now ceaseless. Moreover, the efforts of all private associations and individuals interested in saving the lives of babies are now coordinated in a more effective way than ever before, by the Babies' Welfare Association.

**Plans for the Coming Summer.**

The methods which have been referred to will be carried out during the coming summer under all the advantages of accumulated experience and improved organization. At each of the fifty-five milk stations a nurse is on duty all the time and a doctor is on duty two days each week. On May 1st an additional nurse was assigned to each station for the extra work of the summer months. The milk stations are being developed constantly toward the ideal of educational centres, and breast feeding particularly is encouraged as far as possible. The number of mothers who now come to the stations in order to obtain milk for themselves, so that they may nurse their babies, is encouragingly large.

On July 1st, all of the nurses now doing school work will be assigned to duty in the instruction of mothers. Each nurse will have 150 babies to care for, and will work in a district which is not already covered by the activities radiating from an infants' milk station. This custom has been followed for the past two years with great success; the nurse visiting the baby as soon as possible after it is born and keeping it under continued observation during the hot weather. Every morning each group of two or three nurses meets with the department physician and consults with him regarding delicate or sick babies. If a child is not normal, the medical inspector visits it himself and refers the family to the proper dispensary or hospital to have the baby treated, if necessary. In 1912, 38,000 babies were treated and 1,600,000 quarts of milk were dispensed at these stations.

Beginning this week, lectures on the care of babies are being given in all the public schools to all girls over twelve years of age, in order to enlist their interest in the formation of the Little Mothers' Leagues. These educational groups will be kept together during the summer, as usual, by weekly lectures and demonstrations by the nurses and doctors of the department.

The same splendid cooperation of private agencies which has been given hitherto is expected this year. About eighty different agencies are now federated in the Babies' Welfare Association, with its central clearing house for information and publicity at the headquarters of the Department of Health.
PURE MILK.

In addition to the specific preventive work, the efforts of the department to steadily raise the sanitary quality of New York’s milk supply constitute an important factor in lowering the infantile death rate. The strenuous campaign for the extension of pasteurization, which has been made the first object of the Department of Health during the present administration, has had a marked effect, and the proportion of pasteurized milk to the total supply has risen from fifteen per cent. to fifty per cent. in two years. In round numbers this is equivalent to an increase in pasteurized milk from 300,000 to 900,000 quarts out of the daily supply. The latest step in the direction of pasteurization has been the adoption of the requirement that after July 1, 1913, cream shall be pasteurized, unless it is obtained from Grade A or Grade B milk. Increasingly stringent regulations of the sale of “loose” or “dipped” milk is also an important factor in the programme of the department.

THE RELATIONS OF ADHESIONS AND INTESTINAL ANGULATIONS RESULTING FROM ENTEROPTOSIS, TO CHRONIC CONSTIPATION.

Personal Observations.*

By ROBERT COLEMAN KEMP, M.D.,
New York,
Professor of Gastrointestinal Diseases at the Fordham University Medical School; Consulting Physician (Gastroenterologist) to the Manhattan State Hospital; Visiting Gastroenterologist to the Fordham University Medical School Clinic, etc.

The subject for my paper this evening was selected with the belief that it would prove of interest to the general practitioner as well as to the specialist, and with this object in view, I shall briefly recount a few personal experiences. It may be premised that in what I have to say radiography will play a prominent part. One should take into consideration not only the radiograph, but also the physical signs and symptoms, in making the diagnosis. For example, in a particularly interesting case, showing the transverse colon lying well down in the pelvis, or, rather, a portion of it extending down into that region, there are no evidences of interference by adhesions to the passage of bismuth. The angulations and displacement alone can be determined by the x ray. The physical signs on examination and the history are, however, conclusive. The patient, subsequently to the removal of a diseased appendix, suffered from a local peritonitis, evidently having its origin at the stump of that organ, and she had been persistently tender

Fig. 1.—Case of Mrs. C., showing water trap stomach.

Fig. 2.—Case of Mrs. C., showing enteroptosis; dilated caput coli and ascending colon; angulation at +.
over this region for several years. Unquestionably, there are adhesions binding the descending arm of the transverse colon to the caput coli and the ascending colon; so that the usual medical treatment of the enteroptosis, by application of adhesive strapping or special belt or corset, together with diet to increase the intraabdominal tension by accumulation of fat, etc., will prove of no avail. This serves as an illustration. Advanced cases of chronic stenosis of the intestine can usually be diagnosed without the X rays, but, even so, these should be employed as confirmatory. For the early and positive diagnosis of adhesions producing chronic constipation they are of great value. Prolapse of the abdominal organs can unquestionably be determined by other well known methods, but the actual angulations and distortions can be satisfactorily demonstrated only by the Rontgen rays. One cannot always persuade private patients to submit to such an examination, either on account of the expense or through timidity; or they will insist that the physician should be capable of making a diagnosis without their use. The moral effect on the patient, however, when he can see the actual conditions in the radiograph, is excellent, and he thus becomes more amenable to treatment. The X ray is also of value as an aid to prognosis, and, further, enables the physician to determine whether or not it may be necessary to resort to surgery.

The causes of constipation are too numerous to mention in this paper, and its etiology may, literally, be said to be due to medical and surgical diseases occurring from the brain to the anus. Excluding all other causes, we have as a final classification "constipation due to disturbances of the motor functions of the intestines." This is subdivided into constipation due to retarded intestinal peristalsis—atomic constipation, and constipation due to enterospasm—spastic constipation. Among the predisposing causes of atomic constipation are the type of nourishment taken (food with little residue or constipating food), neglect of the call of nature, interruption of regularity, abuse of cathartics, large enemata, mental conditions, sedentary life, too prolonged exercises, etc. The prevalence of constipation among women is well known. Meynert found in fifty girls, aged twelve, that fifty per cent. suffered from enteroptosis, and that about eighty per cent. of all women in his gynecological clinic had the same complaint; while it occurred in only five per cent. of males. Nephroposis as a result of traumatism, or in the form of congenital floating kidney, the writer believes occurs in only from five per cent. to ten per cent. of all cases; while in the remaining ninety per cent. or ninety-five per cent. it is one of the stigmata of enteroptosis. The late Doctor Edebohls found nephroposis in twenty per cent. of his cases, disregarding associated ptoses, while some even place it as high as thirty-three per cent. In the community at large, the writer believes, at least from fifteen per cent. to twenty per cent. of all women have enteroptosis, and he has found that fully thirty per cent. or thirty-five per cent. of women coming to him for treatment of the gastrointestinal tract are sufferers from this condition. In these cases the musculature of the stomach and intestines, and also the muscles of the abdominal walls, are relapsed, and these factors have also a bearing in the production of atomic constipation. The stigmata of typical cases of enteroptosis are readily recognized at sight, but many of the milder cases are apt to be overlooked by the general practitioner; or a diagnosis of nephroposis alone is made, and, in many cases, simply "atomic constipation." The more moderate types of angulation from enteroptosis, the writer believes, have a bearing on the disturbances of motility of the intestines resulting in the symptoms of so called atomic constipation. The X rays readily de-
monstrate the condition to the satisfaction of the patient, as well as the physician, and correction of the enteroptosis relieves or cures the constipation. It is a well-known fact that perigastric adhesions involving not merely the pylorus but other regions of the stomach interfere with the motility of that organ and disturb its secretion. It is my belief that frequently adhesions affecting the intestines, of slight or moderate degree, not sufficient to cause stenosis of the intestines, are often a cause of disturbance of their motor and secretory functions. In effect, therefore, careful investigation will demonstrate in quite a large proportion of cases of so-called atonic constipation, that enteroptosis with moderate angulations or that slight adhesions are factors.

As to spastic constipation, it may be stated that diffuse enterospasm involving the small intestine occurs with spinal meningitis, diseases of the pons and medulla, and chronic lead poisoning; the abdomen being retracted like a trough. Localized, or circumscribed, enterospasm is more frequent, and generally affects a portion of the large intestine. Spastic constipation occurs most frequently in nervous patients, in true neurasthenics, and in the aged and debilitated. It is found as a sequell to chronic dysentery and ulcerative colitis and in cases of hysteria and neurasthenia in women, associated with uterine disease. In view of the fact that, as already noted, Meynert reports that about eighty per cent. of all his gynecological patients suffer from enteroptosis, the statement made above is, to say the least, suggestive. Stenosis, also, results from ulcerative conditions, and intermittent attacks of colic, with increased peristalsis above the stenosed region, may occur, with fecal accumulation above the point of narrowing in the gut. The writer believes that adhesions with narrowing of the intestinal canal, as well as enteroptosis with marked angulations, are frequent factors in the production of so-called spastic constipation. He has seen the typical symptoms, with the evacuation of small balls (goat feces), or pencil-shaped material, occur in the conditions stated above.

Therefore, a careful study of so-called atonic and spastic constipation will demonstrate that many of these cases are due to adhesions or to angulations from enteroptosis; the atonic type of constipation resulting from the lesser degree of these conditions, interfering with intestinal motility; and the spastic type, due to more marked adhesions, or angulations. All cases of chronic constipation should be carefully studied with the x-rays, and it is this statement which the writer is desirous to impress particularly upon his audience.

I shall not describe Lane's kinks or Jackson's membrane, which are doubtless familiar to you all, but merely give a brief résumé of our cases. They are of interest, since any physician present may meet similar types in his practice, and they emphasize the necessity of careful investigation of all causes of chronic constipation. I shall not burden you with long histories, the bacteriology of the stool, etc., but simply refer to the salient symptoms. I have observed that long drawn out histories are likely to produce a "soporific effect" on the audience:

CASE I. Mrs. C., aged forty-eight years, referred by Doctor Tousey. Ill for fifteen years; belched gas; very nervous; marked constipation, usually atonic in type; occasional attacks of intestinal catarrh with colic; had had two pelvic operations and asserted that adhesions were found on both occasions. Urine, indicanuria persistent; stool, putrefaction. Hyperchlorhydria—total acidity 90+; free hydrochloric acid 50+; combined hydrochloric acid 40+; total hydrochloric acid 90+. Physical examination showed gastroposis and enteroptosis, but no angulation could be determined.

Radiograph by Doctor Tousey: Water trap stomach, enteroptosis (Figs. 1 and 2).—Stomach has a long vertical limb; horizontal limb short, at level of umbilicus; a

FIG. 5.—Case of Miss D., showing marked enteroptosis; sigmoid rising to umbilicus; bismuth by enema.

FIG. 6.—Case of Mrs. E., showing normal position of transverse colon; caput narrow and low; hepatic flexure low; adhesions to transverse colon at +, near level of umbilicus; splenic flexure in normal high position.
A.K., showing vertical stomach with hourglass contraction; adhesions.
it might help absorption of the adhesions. Of its value I was skeptical. She was warned to always have the radiograph at hand and in the event of progressive constipation to at once consult a surgeon and show him this.

Case IV. Mrs. E., aged thirty-six years, referred by Doctor Peck, of New Rochelle. This patient had an attack of acute appendicitis ten years ago. Off and on for three years she had had vomiting spells, occurring most frequently near or at her periods, and usually one to two hours after meals. No real nausea; vomiting acid; no blood visible. Pain occurred at the time of the attacks and food relieved this; there was also epigastric pain after the vomiting. Patient fairly comfortable between attacks, and bowels fairly regular; during the attacks she was costive. Physical examination showed the right Fallopian tube to be tender; appendix also sensitive; uterus retroverted and enlarged, presenting a fibroid condition. Gastric analyses average total acidity 90+ to 100+; free hydrochloric acid 50+; combined hydrochloric acid 40 to 45+; no occult blood; tests for augmented secretion negative. Urine, indicanuria; stool, intestinal putrefaction; no occult blood. Hemoglobin eighty per cent. The patient unfortunately had no attack while in the hospital.

Radiograph by Doctor Tousey.—Radiograph showed the caput coli to be narrow and low; hepatic flexure low; transverse colon passing across umbilicus; splenic flexure in normal position. Adhesions to transverse colon shown by interference with the passage of bismuth. (Fig. 6.)

The writer believes that the web of adhesions probably originated from the region of the appendix and that the gastric symptoms were reflex from the chronic appendicitis, adhesions, and uterine condition. Disturbance of the motility of the intestines, with constipation, occurred when the gastric symptoms were pronounced. Operation on the adhesions, appendix, and uterus was advised.

Case V. Mrs. McM., aged forty-six years, referred by Doctor Gonzales. The patient suffered from obstinate constipation apparently of the atonic type. There was a history of previous attacks of peritonitis. Physical examination showed narrowing at the sigmoidorectal junction, probably due to adhesions. Nothing further could be determined by the ordinary methods of examination.

Radiograph by Doctor Tousey.—Radiograph (Fig. 7) showed marked adhesions at the transverse colon (considerable interference with passage of the bismuth at this point); also the caput coli and ascending colon to be considerably dilated. Hepatic flexure normal in position; slight adhesions at sigmoidorectal junction.

Operation by Dr. Parker Sym's confirmed the diagnosis. The patient did well for some months, the bowels markedly improving. There was then a recurrence of the constipation. The radiograph taken by Doctor Tousey at this time showed a recurrence of adhesions at the transverse colon. A second operation by Doctor Sym's confirmed their presence and they were again separated. Marked adhesions, however, were also discovered between several coils of the small intestines and the abdominal wall on the left side, as well as adhesions to the ascending colon, but my recollection is that there was one mass of adhesions which it was considered inadvisable to operate upon. Doctor Sym's can give you full particulars.

The constipation then again improved, after this second operation. Doctor Gonzales now reports the patient in excellent condition.

Case VI. Miss A. K., aged fifty-one years, referred by Doctor Mucklow, of Brooklyn. In October, 1911, the patient began to have nausea and later vomiting, both during the night and in the day time. She had eaten some hours before. At times she vomited clear, watery material, though it was often yellow and sour to the taste. It is stated that she visited a specialist in diseases of the stomach in Brooklyn, who made the diagnosis of chronic appendicitis with pylorospasm. An operation showed that she had chronic appendicitis and pericarditis affecting the ascending colon. Many adhesion bands were separated, and the appendix was removed. The patient improved for a brief period, but nausea and distress later returned, coming on one hour after meals. The doctor then took charge of the case and, determining that there was enterotropism and believing that this was a factor in producing the symptoms, applied Rose's belt and the usual treatment for this condition. The symptoms, however, continued, and in January, 1913, he brought the patient to my office. At this time the nausea and distress after meals were still in evidence, there was pain over the right kidney, and the patient suffered from severe constipation. Physical examination showed a movable right kidney, enterotropism, and apparently a semioblique stomach (mild gastroprosis). On account of the history the writer believed adhesions had reformed in the appendicular region and gave this as his diagnosis, in addition to enterotropism. Total acidity 70+; free hydrochloric acid 304+; combined hydrochloric acid 35+. The gastric symptoms were believed to be reflex from adhesions.

Radiograph by Doctor Tousey.—Radiograph (Fig. 8) showed a vertical hour glass stomach. The latter condition had been unsuspected, and was evidently due to adhesions. The lower gastric border did not reach the level of the umbilicus. There was an enterotropism with angulations and adhesions (Fig. 10); the ascending colon was short and the hepatic flexure lower than normal. The descending arm

FIG. 9.—Case of Miss A. K., showing enteroptosis; sigmoid flexure lying in pelvis; small bismuth enema.
of the transverse colon was vertical and parallel with the ascending colon; it was sharply angulated where it turned to cross the abdomen, and just above this point there were adhesions interfering with the passage of bismuth and evidently binding the descending arm to the ascending colon. On the left side there was a sharp angulation where the transverse colon turned upward. In its course to the splenic flexure, it lay parallel with and contiguous to the descending colon. The transverse arm crossed the abdomen about two and one half fingers' breadth below the umbilicus. The splenic flexure lay high up, and there was a sharp angulation at this point. The descending colon lay side by side with the ascending arm of the transverse colon, as previously noted, while the sigmoid flexure lay in the pelvis. (Fig. 9.)

Operation was advised by the writer. Apparently the operation of selection, would be an enterocutostomy at each end of the transverse arm—short circuiting the portions of the colon above and avoiding the adhesions which lay just above the appendicular region. Operative procedure was also indicated on the stomach.

Radiograph by Doctor Toosey.—(Fig. 11) is of interest as demonstrating the presence of a small gastric ulcer secondary to gallbladder infection. Other methods of diagnosis had proved failures.

There are many interesting features in these cases. Abnormalities in gastric secretion, when there is gastroptosis, the writer believes, from careful investigations carried on at the Manhattan State Hospital, are due to the misplaced stomach. He has reported in his work on gastrointestinal diseases the disappearance of hyperchlorhydria, after repeated application of Rose's belt alone. In patients with intestinal adhesions, functional disturbances of the stomach he believes to be, in most cases, a reflex from these adhesions; just as such reflexes occur from disease of the appendix or gallbladder. Many instances of so called atomic constipation he attributes to slight or moderate angulations from enteroptosis, or to slight adhesions—that is, adhesions not producing stenosis, but merely interference with the motility of the intestines. On the other hand, more marked angulations or adhesions may, in some cases, produce the symptoms of spastic constipation—suggestive of commencing or mild stenosis. Unquestionably, correction of an enterocutostomy, uncomplicated by adhesions by medical means, such as belts, corsets, adhesive strapping, and the increase of intraabdominal fat, will do much for the constipation in some cases; while cases of enteroptosis which cannot be relieved by these means belong to the domain of surgery. All cases due to adhesions should be referred to the surgeon.

Surgery. Regarding the question of surgery, the writer desires to present some problems for discussion this evening: the first in regard to adhesions. In the two operations for adhesions, both being performed by skillful surgeons, the adhesions formed again, thus necessitating a second operation on both patients. Would it be preferable in such cases to short circuit the intestines by enterocutostomy, and leave the adhesions undisturbed? In such event, what probability would there be of torsion of the gut, or of some other portion of the intestine than the affected part slipping beneath the adhesions or becoming adherent to them?

Second: In the case of enterocutostomy with marked angulations, there is always great redundancy of the transverse colon, and suspension of the intestine would seem in some instances to be impracticable, while revision of the recti muscles would seem equally so. Would a double enterocutostomy, thus short circuiting the angulations, be preferable? In one of my cases, even if this procedure had been carried out, there would still have remained the sigmoid flexure completely collapsed and angulated and lying in the pelvis. The additional problem would then remain, whether to resect, to short circuit, or to suspend the sigmoid. Unless some such procedure were carried out, there would probably be still sufficient mechanical obstruction to produce constipation.

It has been my endeavor this evening to demonstrate not only the great value, but also the necessity, of careful examination by means of the Roentgen rays of all patients in cases of chronic constipation, and if I have succeeded in impressing this fact upon my hearers I shall feel that I have fulfilled my task.

103 East Fifty-Seventh Street.

SOME RADIOGRAPHS OF OBSCURE STOMACH AND INTESTINAL CASES.

Caution Regarding Dangerous Tendencies in Recent Radiography of the Gastrointestinal Tract.*

By Sinclair Toosey, A.M., M.D.

New York.

The primary facts regarding x ray diagnosis of these cases are familiar to all of us. The patient

*Read before the Medical Association of the Greater City of New York, April 21, 1913.
comes with the stomach and intestine empty. No solid food and no milk are taken for thirty-six hours prior to the examination, and the bowels are moved by a laxative the night before the examination, and in many cases the night before that. A meal consisting of mashed potato, a glass of water, and an ounce or an ounce and a half of bismuth oxychloride forms an accurate mold of the stomach and casts such a dense shadow in the radiograph as to show the size, shape, and position of the stomach. Dislocation, ptosis, or displacement downward, and hourglass constrictions are evident at a glance, as seen in some of the radiographs shown to-night. Other lesions, like cancer, are indicated by changes in the outline of the stomach, changes in the time required to empty itself; and in the case of ulcer of the stomach, or ulcerative cancer, by bismuth remaining adherent to a portion of the stomach wall after the contents in general have passed on into the intestine. (Fig. 11. Doctor Kemp's paper.) Obstruction and ulcer in the duodenum and other parts of the small intestine are shown by radiographs made at various times after a bismuth meal. The best demonstration of lesions of the rectum, the sigmoid flexure, the descending, transverse, and ascending colon, and the cecum is by a radiograph made after a bismuth or barium enema. A radiograph of mine which shows the rectum and sigmoid flexure was made after an injection of barium sulphate, purified for radiological use and suspended in a thick decoction of potato flour. This formed a pasty mass which ran very slowly from a fountain syringe and filled only the required part of the intestine. The radiographs are specifically referred to in Doctor Kemp's portion of this paper.

Dangers tendencies in recent x ray work upon the gastrointestinal tract lie chiefly in the use of the fluoroscope and in the making of multiple radiographs of the same patient. The voice of the tempter tells us that we can watch the progress of a bismuth meal with the fluoroscope, while the patient is exposed to a radiance which would not hurt him if applied all day, and that when different important stages are observed the photographic plate may be substituted for the fluorescent screen and a radiograph be made with a stronger ray applied for a fraction of a second. It is very far from being true, however, that any ray which gives a perceptible fluoroscopic image through the abdomen can be safely applied indefinitely. I do not permit this at all in my x ray laboratory; but if I did, it would be on condition that the dose of the radiance used for fluoroscopy should be measured, and the safe time of exposure determined beforehand and strict account made of each second's exposure. Of course the fluoroscopic screen should be observed in a mirror while the operator is protected from the x ray by a lead shield.

Another dangerous use of the fluoroscope is in a preliminary observation to facilitate the location of the patient, the x ray tube, and the plate, in the effort to secure the picture of the desired portion, say the stomach, upon a plate of rather small size, say eight by ten inches. The varying size and position of the stomach make it difficult to be sure of a good picture upon a plate of this size, but the author is so certain of the danger of fluoroscopy that he avoids it by using a larger plate. This would not be so practicable for an attempt at cinematography, but, as will be seen later, the author thinks this undesirable. The matter of clear definition over a larger plate is secured by means of a flat diaphragm of say two and three quarters by three and one quarter inch orifice directly in contact with the wall of the x ray tube. The diaphragm is of material opaque to the x ray, but not a conductor of electricity. The objection to multiple radiographs, and especially cinematographs, is the danger of overexposure. It is less than ten years since the radiologist of one of our largest institutions told the author that he never attempted a radiograph of the hip joint because his apparatus required an exposure of forty-five minutes, and patients knew that it was done elsewhere in about seven minutes, and were afraid of being burnt. As a matter of fact, the patient was subjected to the same amount of x ray by the exposure of seven minutes with the stronger apparatus as by the forty-five minutes' exposure with the weaker apparatus. And to-day, with vastly more powerful apparatus, the patient is exposed to the same amount of x ray in a second or two.

Just as there was a very distinct limitation to the number of pictures that could be safely made through the abdomen with the long, weak exposures, there is also about the same limit with the short, strong exposures of to-day; and because it is easy to give the exposures in rapid succession, there is danger that the safe dose may be exceeded. The individual exposure may be reduced to a small fraction of a second by the use of an intensifying screen. These screens differ so much in efficiency that the exposure may be one half or perhaps only one tenth that required without the screen. This means that from two to ten times as many pictures may be safely made as without an intensifying screen. But when it comes to twenty, thirty, or forty radiographs, as in radiocinematography, one is dealing with a dose which should be exactly measured, and its effect upon the individual patient most carefully considered before applying it. The author has made measurements of the x radiance from all the modern transformers and from the unfluctuating converter which is partly his own invention. At a distance of ten inches from the anticathode to the skin, and with the current usually employed in rapid radiography, most of these reach the danger limit as to burns in ten or twenty seconds; so that a great many exposures, even though each lasts only a fraction of a second, present a danger from dermatitis and may have an undesirable effect upon the general system.

The modern apparatus makes it possible to make individual pictures of moving organs like the stomach, and this may be repeated at different stages of digestion, but I think it dangerous to make a very large number of exposures to show the actual motions of the organs.

850 Seventh Avenue.
TORPOR RECTI; DYSCHEZIA.

A Contribution to the Pathogenesis of Habitual Constipation.

BY GUSTAV SINGER, M.D.,
Vienna, Austria,
Professor, University of Vienna; Primarius, First Medical Division, Rudolf Hospital.

The treatment of constipation has always been a favorite field of research with qualified and unqualified practitioners. In the insistence on evacuation by way of the bowels is shown the great importance attached by the physicians of old to the regular evacuation of these by invalids, as well as by healthy persons. While the therapeutic measures of habitual chronic constipation have long been a subject of research in the laboratories of experimental pharmacologists, it is astonishing that it is only in the last few years that scientific medicine has endeavored to remove the prevailing vagueness in the knowledge of the subject by experience obtained from exact examinations. In this article, intended only for the practitioner, I wish to avoid discussions of controversial views and only to speak on one particular point, which must be regarded as an assured result, both for our comprehension of this form of ailment and for its therapeutics. One who is accustomed to examine the rectums of many patients, whether they complain of constipation or not, will find, partly by digital palpation and partly by endoscopic methods, marked differences in the conditions present.

In many persons, even those who are suffering from obstinate constipation, we find the rectum, including the ampullar portion, empty or occupied only by insignificant fragments of feces. The extreme on the other hand is characterized by the presence of large masses of compact or loose feces, distending the ampulla and often reaching to the external sphincter. This condition of affairs is found remarkably often in women, with or without genitai affections, and the question has been asked what connection can exist between the presence of feces in the rectum and the physiological or abnormal evacuation of the bowels. Samuel G. Gant tells us in his Fecal Impaction that in about sixty per cent. of the cases of constipation impaction of feces is to be found in the rectum, and Esbein, holding the same opinion, has described a peculiar method of palpation by means of which we can feel this accumulation of feces between the gluteal fold and the point of the coccyx without penetrating into the anus.

Henle, Hyrtl, and O'Beirne have discussed the question of the normal state of the rectum, empty or filled, but without going into any recital of this discussion, I will express my conviction that the famous anatomist Hyrtl was undoubtedly correct in his conclusions. I myself have never found, under normal conditions, any noteworthy impaction of feces in the rectum, and therefore believe I am justified in saying that the normal state of the rectum is emptiness. The examination of the physiology of the act of defecation made in experiments on animals by Langley, Anderson, and others in conformity with the conditions specified by O'Beirne, has proved that in physiological de-
certain degree to the prompt course of the act (ecceprose). On referring to Adolphe Schmidt’s researches we find that the want of water and the too complete absorption of the contents of the bowels are responsible for defective stimulus of peristalsis. To this class belong those varieties of constipation due to the different qualities of the food; a meat diet, with its small residue on the one hand, and a diet of food rich in cellulose on the other. One must not ignore the fact that cause and effect can be confounded. Even bowel contents in themselves well adapted for evacuation may by various causes be retained for a longer period than normal in the lower intestine, and there become thickened by absorption of water, so that in this way evacuation is rendered still more difficult.

We know from numerous instances that anomalies are met with in the intestines. Some patients, although treated with the most varied diets and those proving very effective in other cases, continue to have a marblelike stool. Hertz designates this condition very expressively as “greedy colon.” Such an anomalous resorption may, I believe, be inherited through several generations, and this must be taken into consideration when we sometimes find young infants afflicted with the most obstinate type of rectal constipation.

In connection with the acquired forms of constipation, it must be mentioned that such ampullar constipation may arise also from weakness of the muscles of the pelvic floor, so that the evacuation of feces is rendered difficult or even impossible. This state is often found in women with severe ptosis and vaginal prolapse, with perineal laceration. Like myself, Hertz has differentiated this particular form of rectal constipation from the complex of habitual constipation and has given to it a special name, which has been generally adopted, dyschezia. Hertz defined with this term the state in which it is impossible to empty the rectum completely. Some part of the stool always remains, and thus the feces accumulate gradually until large masses fill the ampulla. This has been compared to the somewhat similar condition met with in the bladder, and the larger or smaller quantity of feces found in the rectum after defecation has been called by Federn residual feces.

The stimulus excited by such a filled ampulla on the muscular apparatus entrusted with the act of defecation is such that it acts frequently and incompletely, instead of once and thoroughly, a type answering to the fragmentary stool evacuation of Boas. But I must here remark that these and many other symptoms are to be regarded as secondary, and as stimulus called forth only by the stagnant contents of the bowels.

Dyschezia is divided by Hertz into two classes: 1. Insufficient evacuation; 2. the obstacles to a sufficient evacuation. I think that this second class does not strictly belong to the group of ampullar constipation called by me torpor recti. In the first group of causes are: Habitual disregard of the call to defecation, weakness of the voluntary muscles of evacuation, weakness of the reflex defecation; in short, complications completely agreeing to the anomalies caused by the recurring torpor recti above mentioned. Characteristic is the fact that the x rays show the shadow band reaching to the anal exit and a marked distention of the ampulla. I repeat that I do not go as far as Hertz, who includes in dyschezia forms of constipation properly belonging to other conditions.

The name of torpor recti ought really to be reserved for rectal irregularities only, which, as mentioned, result from a defective course of evacuation caused by want of stimulus. The diagnosis of this special form of rectal or proctogenital constipation, as it is called by Strauss, is fairly simple. A description or observation of the stool and digital or endoscopic examination usually suffice. Important is the fact that diet or purgatives are as a rule of no value.

For many years I have used very small enemas, but not with glycerin, on account of the intense irritation caused by it. Water, chamomile tea, warm olive oil, oleum hyoscyami and liquid paraffin, applied morning and evening, are to be highly recommended. The paraffin, spreading over the surface of the bowel membranes, softens the dry feces attached to it and prevents excessive dryness of the contents. For children a cacao butter suppository is often sufficient.

In addition to dilating tubes and bougies used by me in some forms of spasmodic constipation, I would chiefly recommend a form of treatment which was, I think, first recommended by Ewald and introduced into therapeutics under the name lavement electrique. A tubular electrode, furnished at its centre with a metal mandrel, is introduced into the rectum. Two hundred grammes of water are poured into it, and this probe can be charged from either electrical pole, according to the effect desired. A broad, flat electrode is applied alternately to the flexure of the colon and to the cecum. The application lasts ten minutes. After my experience with this method I can say that I have obtained good and lasting results in the most obstinate cases.

A NEW BIOROENTGENOGRAPHIC APPARATUS.*

By I. S. Hirsch, M.D.,
New York,
Röntgenologe, Bellevue Hospital; Lecturer in Röntgenology, Post-Graduate Medical School and Hospital.

The attempts made to obtain kinematoradiographs have been by two general methods. In one, the indirect method, it is sought to photograph the image on the fluorescent screen; by the other, the direct or serial method, a series of radiographs are made, which are then transferred to small films for projection. The difficulties in the first method are great, on account of the inability to obtain lenses of sufficient rapidity to photograph the faint image on the fluorescent screen. The difficulties in the second method are, to obtain a mechanism which will rapidly bring a full size plate opposite the part radiographed, properly expose it, and then remove it safely from the action of the rays, while another plate goes into the proper position for exposure;

*Presented at the meeting of the Bellevue Alumni Association, held March 20, 1913.
the main problem being a mechanical one. There is still a third method, by which it may be possible in the future to achieve the results we are striving for. It is that direct method—which will become possible when some genius shall have succeeded in the focusing of the x rays. This is not as remote as is imagined. That problem, and many others in roentgenology, will then have been completely and finally solved.

As early as 1900 attempts were made to obtain cinemato-radiographic pictures of the fluorescent image, and, by means of the ordinary cinemato-graph, to thus make visible the movements of such organs as the diaphragm, heart, stomach, and intestines. At this time Cavallio, of Paris, was able to obtain radiographic films which, in the cinematographic projection apparatus, showed the movements of the stomach and the intestines in the frog and other animals. In 1901 Eyckman made the first cinematographic radiographs of the act of deglutition. About ten years later Lomond and Comandani, by means of a special quartz objective and a camera, were able to obtain a series of images from the screen picture on a sensitive film which could be used in the cinemato-graph. They obtained sixteen photographs a second. They studied not only intestinal, but joint, movements of small animals.

Various apparatus for the direct method have been devised by Levy-Dorne and Macintyre, Kohler, Haenisch, and of late by Grodel and Rosenthal.

The most feasible method at the present time is the direct serial method. It has a decided advantage over the indirect method, in that more detail is obtained on the plate than can be gotten from the photographing of the fluoroscopic image. The Grodel apparatus was described in 1909, but has not come into use. The Rosenthal apparatus, manufactured in Munich, is the only one of any practical value, and it is being used in several laboratories in Germany. This apparatus makes thirteen plates, size 18 x 24 cm. It was stated that the apparatus was capable of making four exposures a second, but this has never been demonstrated. Twelve or thirteen plates are exposed during the course of a single peristaltic wave, the duration of which varies from twenty to twenty-five seconds.

What is desired in an apparatus of this kind is not only a larger number of plates, but such a rapidity of change as will permit the making of at least three radiographs a second. The apparatus which I have devised will carry from sixteen to thirty-two plates, size 8 x 10 or 10 x 12, and is capable of exposing the active member in from thirty-two to eight seconds. The apparatus consists of a mechanism which carries the plates in an upright position, underneath a lead covered hood. At the side of this hood is a slit, through which the plates fall in front of a lead screen provided with an aluminum window for exposure. Against the other side of this lead screen, opposite the aluminum window, rests the patient, and behind the patient stand the tube stand and tube. The plates, carried in aluminum holders, are moved into position by a motor, pushed out by a mechanical device, remain stationary for a fraction of a second, and are then returned into place behind the hood, while another plate is ejected. A primary switch circuit breaker, with a mechanism for varying the time of exposure from 1/120 to 1/2 second, works in unison with the falling of the plate, and at the end of the thirty-second exposure the circuit is automatically permanently opened. Intensifying screens are not essential: with the aid of a 6 kilo-watt transformer we have been able to make satisfactory stomach exposures without a screen and do instantaneous chest work with ease. The apparatus may be used for the purpose of making stereoscopic radiographs, from one to sixteen sets being possible. These are automatically exposed, by means of a double target tube, the primary circuit breaker being so arranged as to cause a reversal of current at every other exposure.

FISHBERG: NONTUBERCULOUS APICAL LESIONS.

By Maurice Fishberg, M.D.,

New York,

Attending Physician, Tuberculosis Ward, Montefiore Home and Hospital.

Because practically all tuberculous lesions of the lung in adults first manifest themselves in the apices, any deviations from the normal resonance and breath sounds in these regions are apt to suggest phthisis. Most of the patients admitted to sanatoriums and soon discharged as nontuberculous show some defective resonance, altered breath
sounds, and at times râles at the apex; many persons are rejected by examiners for life insurance companies for the same reasons, though the subsequent history of these alleged "tuberculous" persons shows clearly that they would have made good risks had they been accepted. The tuberculosiS clinics and the day and night camps in this city have some patients under treatment who, though showing some signs of apical changes, yet cannot be considered tuberculous if a careful analysis of the history, symptomatic, signs, and course of their trouble is made. It seems that at present, when we are carefully looking for localized and circumscribed lesions at the apex in every one presenting himself for examination or who coughs or is losing flesh from any cause, individuals who are unfortunate in showing differences in resonance and breath sounds when the two pulmonary apices are compared—and there are many such persons to be found among nontuberculous people taken at random—are in danger of being pronounced tuberculous, irrespective of the cause of their apical lesion. I have of late paid special attention to nontuberculous apical lesions, having met with many cases which have given me considerable concern before I could make up my mind as to whether I was dealing with real incipient phthisis or with some innocent process not due to acid fast bacilli and not at all serious. In this paper I shall attempt to discuss these cases and hope to show that there are apical affections which are not tuberculous.

I find that the bulk of apical lesions met with in daily practice are undoubtedly tuberculous in character, yet there are many cases which, though simulating tuberculous disease in a striking manner, have apical lesions which are by no means caused by the tubercle bacillus, and which per se are not at all detrimental to the health and wellbeing of the affected person. The nontuberculous lesions of the apex seen by me can be classified into three groups:

1. Collapse induration, usually found in mouth breathers.

2. Apical catarrhs, often manifesting themselves after an attack of influenza or found in persons suffering from pulmonary emphysema or who are of defective muscular development, especially in women and workers in indoor and dusty occupations.

3. Apical indurations found in persons with heart lesions.

Of these three groups, the first is the most important and the most frequently met with. Krönig, who first described these cases in detail, showed that the lesion was due to collapse of the apical parenchyma, with subsequent induration.\(^1\) We deal here with a purely local, noninfectious lesion which is not due to the tubercle bacillus. Physical exploration of the lung shows dulness and retraction of one apex, usually the right, rough inspiratory murmur, harsh and prolonged expiration, and even true bronchial breathing, with some dry crackling.

The history shows that since childhood the patient has suffered from nasal obstruction or has been a mouth breather. Many give a history of frequent attacks of colds, catarrhs of the nose, throat and bronchi. But in spite of all this the physical development of the patient has been fairly normal, excepting perhaps some retraction and lagging at the upper part of the right chest. These people may live in comparative happiness till they submit to an examination by some one adept in physical diagnosis. They are then apt to be pronounced tuberculous, and even banished to a sanatorium for a cure. This form of apical lesion is most frequently met with among adults between fifteen and forty years of age, though it is not unknown among children under fifteen. They usually give a history of having been sickly children, subject to colds, coughing quite often and expectorating more or less profusely, especially during the morning hours. Many say that they have noted blood streaked sputum, and with some this was the cause for submitting to an examination. Several of my patients have also complained of pains in the chest, palpitation, slight dyspnea, disturbed sleep, and night sweats. One important point is that nearly all of these patients have kept at work, never having been sick to such an extent as to be disabled, as is usually the case with true phthisis. It is only after being frightened by some blood streaked sputum, or by a rejection after a medical examination for life insurance, etc., that these patients become disheartened and may stop working. My experience in New York city leads me to believe that collapse induration is not rare here. Examining over one hundred healthy adults weekly for the last eight years, I have found that there can be elicited differences in the resonance and breath sounds, when the two apices are compared, in about three per cent. of people engaged in indoor occupations. Blumel states that of 1,700 patients who passed through the sanatorium under his care, eighty-five, or five per cent., were not tuberculous. Of these, twenty-eight were cases of collapse induration; the rest were cases of emphysema, bronchiectasis, etc. Thus, one third of the nontuberculous patients admitted to that sanatorium had lesions of the type of collapse induration.\(^2\) I am under the impression that conditions are not different in American institutions, as I have seen many patients of this type that have spent some time in sanatoriums.

The causes of collapse induration have been a fruitful source of speculation for many writers. Krönig shows that it is usually due to the inhalation of dust. Why the apices (especially the right apex) are first affected, is explained by the fact that these parts of the lung, by reason of their anatomical relations, are at a disadvantage which predisposes them to pathological changes to a greater extent than the rest of the lungs. Their location outside the bony thorax, and the peculiar manner in which the bronchi entering the apex branch off from the main bronchus, favor a greater force and pressure of the inspired air in these areas; while the expiratory pressure of the air, lacking the assistance of the ribs and intercostal

---

muscles, is much less in the apices than in the lower lobes of the lungs. The sucking power during inspiration is thus greater to a certain extent in the apices, and because of the larger calibre of the right apical bronchus and its larger number of branches, greater in the right than in the left. The result is that the dust elements of the inspired air are easily deposited in the apices, especially the right. This has been proved experimentally, and also at autopsies in cases of pneumoconiosis—the apices are usually first affected. Nasal obstruction involves mouth breathing, with the following consequences: The inspired air, loaded with vegetable, animal and mineral dust of all kinds, reaches the bronchi directly. Moreover, the inspired air, which normally meets with many obstructions while passing through the upper respiratory passages before reaching the bronchi and is thus warmed and filtered, enters the bronchi and lungs with much greater force in mouth breathers, carrying along dusty elements. The right lung, receiving more air than the left, also gets a larger deposit of dust. In these cases there usually occur, from early childhood, repeated attacks of catarrhal inflammation of the apical mucous membrane which intercede with the entrance of air into the affected areas through the extension of the catarrh from the larger bronchi to the smaller, and finally to the alveoli. This is followed by hyperplasia of the interstitial tissue of the lungs, which is slowly converted into scar tissue, contracting through shrinkage and collapse of the apex of the lung, just as in pneumoconiosis. Collapse induration is consequently a special form of chronic fibrous interstitial bronchiitis of the kind seen in fibroid phthisis, chronic pneumonia, etc.

While in many cases this is undoubtedly true, I am inclined to agree with Wolff-Eisner, who maintains that in many patients the pathological changes are not of an inflammatory character. Indeed, in many cases of nontuberculous apical lesions there is not only dullness, but also distinct signs of catarrh and reflation of the apical isthmus, with pronounced bronchovesicular breathing. Moreover, through respiratory exercises in the open air, as well as by clearing the nasal passages, I have often seen the apex expand again, which could not occur in cases of real inflammatory induration. We may therefore conclude that these apical lesions are often due to collapse atelectasis and not to collapse induration. I am of the opinion that the first stage of this process is catarrhal, due to the irritation of inhaled dust, and in these cases we have atelectasis of the apical alveoli; but when the irritation is continued for years inflammatory changes make their appearance and induration may ensue. This view is confirmed by the fact that young persons under twenty years of age are often cured by the clearing of the nasal passages combined with respiratory exercises, as has been mentioned, while in older persons the pulmonary retraction at the right apex is usually permanent.

More recently Hofbauer has shown experimentally with Marcy’s pneumograph that collapse in duration is due altogether to insufficient respiratory activity of the upper parts of the thorax. Habitual mouth breathers do not at all expand the upper parts of the thorax, and this leads ultimately to collapse of the lung apex, absorption of the air in that area, etc. 1

The differential diagnosis between tuberculous and nontuberculous apical lesions of the character just described only rarely presents great difficulties if the following points are borne in mind: In tuberculosis we have usually a history of exposure to infection, mostly in the family, while in the nontuberculous cases this is usually lacking. In most of the cases of collapse induration the patients have suffered from nasal obstruction since childhood, and generally have enlarged turbinate bones, nasal polypi, adenoids, or enlarged tonsils. They complain that they have not been able to breathe through the nose for years, have expectorated considerably, suffered from dryness and itching of the throat, and had a strong tendency to colds, tonsillitis, and frequent bronchial catarrh. The classical facets of the mouth breather is often seen in these patients—open mouth, enlarged and drooping lip, absence of the nasolabial fold, etc. In tuberculosis all this is usually absent. In addition to the absence of tubercle bacilli and the negative allum reaction in the nontuberculous cases of apical lesion, the sputum also shows distinct evidences that it is derived from the upper respiratory tract. It is watery, mixed with saliva, and colorless; sometimes containing grey or bluish globules, not unlike the kind seen in pneumoconiosis. Microscopically there are often found epithelial cells from the mouth, nose and throat, but no tubercle bacilli. The cough in tuberculous patients is apt to provoke vomiting, which is never the case with collapse induration. In patients who complained of hemoptysis, I have observed that only blood streaked sputum was expectorated, and not pure blood. What helped me most in distinguishing these cases from those of true pulmonary hemorrhages was that in all these cases the blood made its appearance in the sputum only during an acute attack of rhinitis, pharyngitis, or tonsillitis, while in true phthisis the nose and throat are usually normal during hemoptysis.

The physical signs of collapse induration can not always be distinguished from those of incipient tuberculosis. We may have, as has been stated, some lagging and depression in the supraclavicular space of the right side; dullness with narrowing of the field of resonance, rough inspiratory and prolonged or harsh expiratory murmurs, bronchovesicular breathing, and sometimes even true bronchial breathing. In many cases I have heard whopered bronchophony anteriorly, beneath the inner third of the clavicle, and posteriorly in the suprascapular fossa, especially near the spine. Râles are not frequent. Occasionally we hear some dry clackings, or shihation, localized and circumscribed at the seat of the lesion, and persistent, just as in some cases of incipient tuberculosis. Moist, subcrepita t râles are very rare, and whenever I have heard them in these cases I almost always could convince myself

that they were transmitted from the nose and throat. In the patient breathing with an open mouth, cough, with clearing of the throat and nose, often brings about the disappearance of the râles, thus indicating that they do not have their origin in the secretion of the small bronchi, or in atelectasis of the alveoli, but in the nose and throat. In tuberculous lesions cough increases the râles, and often provokes râles when they are absent during ordinary or forced breathing. König insists that the best and most reliable sign which distinguishes collapse induration from incipient tuberculosis is that in the former the motion of the base is normal, while in the latter it is restricted. But I have seen many cases of tuberculosis, even in the moderately advanced stage, in which the motion of the base was quite normal. Several important points are of great assistance in our attempts to differentiate these cases from tuberculosis. To begin with, the general appearance of the patient is rather good, in spite of the fact that he gives a history of cough, pain in the chest, etc., for months or years; he is well nourished and does not lose weight, as is usually the case with progressive phthisis. He is able to keep at his work, and the sense of fatigue and languor characteristic of tuberculosis is usually lacking. Moreover there is no fever, which, when carefully looked for, is discovered in practically every case of incipient tuberculosis. Nor is there any tachycardia and instability of the pulse which are only rarely absent in tuberculosis. The patient is not sick and in the vast majority of cases can be speedily relieved of his cough, expectoration, etc., by a slight operation—clearing the nasal passages, tonsillectomy, removal of adenoids, or polypi.

The question whether there are circumscribed apical catarrhs of a nontuberculous nature has been discussed quite extensively. Some writers would like to banish this term from medical nomenclature. On the other hand, there are many who can speak with authority and who recognize that there are often met with local catarrhs of the apex which are not caused by the tubercle bacillus and are altogether innocuous. My experience among workers indoors and dusty occupations, like tailors, furriers, carpenters, iron workers, etc., has taught me that there are nontuberculous apical catarrhs, especially in persons who suffer from mild forms of pulmonary emphysema, and they are often mistaken for subjects of tuberculosis and treated as such. In recent years several writers have described these apical catarrhs in detail. F. Müller speaks of a chronic pneumatic local process in the apex which can be mistaken for tuberculosis because of constant crepitation, but which at autopsy shows that it is not due to tubercle bacilli, but to streptococci. F. Kohler mentions similar cases. Among many who speak of catarrhal signs of the apex after influenza and whooping cough König may be mentioned. He shows that these catarrhal signs disappear within a few weeks. He also mentions small bronchietatic cavities at the apex which may cause crepitation for years, especially during coughing spells. Laser, in a recent paper, points out that among women and also in some debilitated men there is often heard harsh breath sounds, especially a loud and prolonged expiratory murmur over the right supraspinous fossa, and occasionally a short note on percussion. He insists that these signs must not be taken for evidences of a tuberculous lesion of that apex, because they are mostly due to other causes.5 More recently Küllis has described in detail a series of cases of apical catarrh occurring in emphysematous young men. He also finds that the crepitation is heard mostly in the right apex posteriorly and is due to local bronchitis and tracheitis. The crepitation may be localized and constant, and thus suggest tuberculosis.

These cases are not at all rare in this city. I see them often in my daily practice. Usually the patients have been examined by some careful physician acting for a life insurance company, or for admission to some fraternal society, and have been rejected because of "lung trouble." Some call for examination complaining of some mild cough and expectoration. Examination shows no retraction on inspection, and normal resonance on percussion; rarely a short note over the right apex, but never a narrowing of the resonant field. But on auscultation we find rough, interrupted, or cogwheel breathing during inspiration, prolonged expiration, and crepitant râles during or at the end of inspiration which may be provoked or increased by coughing. It is remarkable that these signs may persist for months in an individual without inconveniencing him in the least. I have a patient in whom these apical changes have existed for four years, yet she feels quite well and has not lost a day from her work, that of a stenographer. In another woman, whose husband died from tuberculosis, she nursing him through a long illness, such apical signs have given me considerable concern, and only after observing that for a year the patient remained well, could I decide in favor of apical, nontuberculous catarrh. It is important to remember that in these cases there is no retraction, no lapping, and no atrophy of the muscles, which is so frequent in tuberculosis of a few months standing, while the temperature and pulse remain normal. An inquiry into the history of these patients shows that they have been subject to frequent colds, coughs, more annoying during the night, expectoration, and some dyspnea during the spring and autumn months. During such colds, which may last for a few weeks or a month, the patient may suffer from anorexia, weakness, etc., with some loss of weight; the condition thus simulating tuberculosis in a striking manner. Yet, he recuperates and regains his normal weight within a few weeks. In fact, those in whom a diagnosis of tuberculosis is erroneously made, and who are thus induced to take greater care of their health, often put on weight far above their normal standards.

The temperature is always normal in these cases, which is an important point in distinguishing them from pulmonary tuberculosis. The same is true of

---

1. F. Müller: "Die Diagnose der Lungentuberkulose. V. Versammlung der Tuberkulose Ärzte, Munich, 1908.
the pulse rate, which remains normal, while in tuberculosis an unstable pulse is the rule. An examination of the nose and throat may show some mild local inflammatory changes, like redness and swelling of the mucous membrane, indicating pharyngitis or tracheitis and sometimes enlarged tonsils, but only rarely do we meet with pronounced nasal obstruction and mouth breathing, as in cases of collapse induration, which were discussed above. From the latter these cases of simple apical catarrh are also distinguished by the fact that there is no dullness, nor any signs of narrowing of the field of resonance, or distinct retraction; while a short note over the apex is extremely rare; in fact, I have quite often found a note of increased resonance over an apex which was the seat of an apical catarrh. It is also to be borne in mind that the vast majority of apical catarrhs disappear within a few weeks, or a month, while collapse induration persists—the dullness and retraction remain indefinitely unless replaced by emphysema. In short, simple catarrh is differentiated from incipient phthisis by the absence of tubercle bacilli in the sputum, the negative albumin reaction, the normal temperature and pulse, and the rarity of persistent loss of weight, which even if it does occur, is regained within a few weeks of rest and outdoor life. Küble, who has described similar cases, finds that the tuberculin reaction is invariably negative, while the radiogram shows nothing abnormal at the apex. However, these cases are now and then dignosticated as tuberculous and the patients kept under treatment in clinics for weeks; some are even admitted to sanatoria and either soon discharged as nontuberculous, or kept for several months and discharged as “cured,” or more modestly, as “apparently cured.” Küble found among twenty-two of his patients with simple apical catarrh that eight had undergone a cure at sanatoriums. I have seen many more. Some have gone to the mountains or as far as the Rocky Mountains or Southern California, and returned within a few months believing that the climate of these regions had cured them.

The causes of the alteration of the breath and adventitious sounds in these cases are not definitely known. The striking harshness and loudness of the breath sounds, the rough interrupted inspiration, and the prolonged expiration, which is sometimes bronchial in character, are ascribed by Küble to the poor muscular development of his patients, which he says contributes greatly to the striking conduc-
tion of the breath sounds and adventitious sounds. But I have seen these phenomena in persons with good muscles and considerable adiposity, and am inclined to attribute the physical signs in these pati-
ents to the catarrh of the finer bronchial tubes of the affected apex—their mucous membranes are swollen, thus producing stenosis which increases the breath sounds. The rales are produced in a similar manner by the secretion, or by the opening of the collapsed alveoli by the inspired air. In some cases I was convinced that the adventitious sounds were transmitted from the mouth, throat or trachea; but ordinary care easily obviates such a mistake.

There remains yet to be discussed the apical changes often found in cases of heart disease and of nephritis which are at times mistaken for tuber-
culus. It is agreed that patients suffering from congenital heart disease (pulmonary stenosis) and who survive the age of infancy and childhood, often succumb during adolescence to tuberculosis because of the deficient circulation of blood and lymph in the lungs which this cardiac defect brings about. On the other hand, disease of the left heart, especially mitral stenosis, is only rarely complicated by tuberculosis, and this is more striking when we bear in mind that lesions of the left heart are most frequent in early life, the period when tuberculosis is also most common. In 1846 Rokitansky stated that valvular disease is invariably antagonistic to phthisis, while later Traube modified this statement to the effect that only mitral stenosis can thus be credited. Fagge also held that mitral stenosis is an almost complete bar to tuberculosis, the post mortem record of Guy’s Hospital supplying only four cases in the course of thirty years. Kidd’s statistics give one instance only in 500 cases, and Walsh’s one in 130 cases. While these statements may give the impression of too great rarity, because we occasionally meet with a case of mitral stenosis complicated by phthisis, we must be extremely careful before pronouncing a case tuber-
culous when we find a defect in the mitral valve. It is, however, remarkable that many cases of mitral disease are mistaken for tuberculosis, especially at present when the apices are so carefully scrutinized for signs of phthisis. And signs are found at times in the apices because degeneration of the cardia-

culose muscle, and especially mitral stenosis, very often produce congestion or even induration of one or both pulmonary apices. That this is not borne in mind by many of those who should be familiar with such a condition is attested by the fact that many cases of mitral stenosis are treated for months and years in the tuberculosis clinics and day camps of this city. I see every year about a dozen such “consumptives” who are being annoyed by inspectors and nurses of the Health Department, and are refused shelter in case they have to live with strangers, etc. Of the many cases of this character that have come under my observation, I shall mention but one which I saw while preparing this paper:

M. B., thirty-five years of age, tailor. Family and personal history negative, excepting that he had typhoid fever fifteen years ago. Did not recall ever having had rheu-

matism. Three years ago he began to cough and expec-
torate bloodstreaked sputum and to suffer from dyspnea on the slightest exertion. This dyspnea had been increased in intensity, until he became a semiinvalid, and orthopnea was at times so severe that he was obliged to sit up the greater part of the night. His cough was moderate, his expectoration rather scanty, but at times tinged with blood.

Two years ago his physician reported him to the Health Department as tuberculous; a nurse called and advised him to take treatment at one of the clinics. Ever since he has been visited at regular intervals, his family visited him against intimate contact with him, etc. Examination showed a case of mitral stenosis, with a loud presystolic and feeble systolic murmur with maximum intensity at the apex, which was displaced downward and outward; also cardiac hypertrophy, enlargement of the liver, edema of the ankles, etc. Percussion of the lungs showed defective resonance of left apex above the second rib anteriorly and in the supraspinous fossa posteriorly. Bronchocele pulmonary heart sounds, some slight rales, and some expiration in the same region after coughing. Fluoroscopic examination showed a shadow at the left apex, thus confirming the findings by auscultation and percussion. That the process
at that apex was not tuberculous was evidenced by the fact that at no time did this patient have any fever, night sweats, etc. Also he maintained his weight during the two years, and several examinations of the sputum did not show any tubercle bacilli. Yet an inquiry at the tuberculosis clinic at which he had been under treatment brought forth the information that this patient had a tuberculous infiltration of the left apex, in spite of the fact that repeated examinations of the sputum gave negative results.

That the apical signs shown in this case are not of tuberculous nature is also confirmed by the fact that in most cases of mirital disease there is some alteration in resonance and breath sounds at one or both apices. Some simulate tuberculosis to such an extent that the patients are admitted to sanatoriums and hospitals and kept under observation for months before tuberculosis is excluded. At the Montefiore Home and Hospital we sometimes get this sort of cases in the tuberculosis ward. In one case it was very difficult to exclude tuberculosis, and in another similar case the patient was admitted to this hospital after having spent two years in another institution for advanced tuberculosis. The pulmonary signs in the latter case simulated tuberculosis to an extreme degree, yet on autopsy it was shown that there was only a heart lesion, while the lungs were free from any lesion suggestive of present or past tuberculosis. Similar cases have been reported by Caussade and Questre. I have carefully examined the cases of mirital disease that have come under my observation within the past six months, and found that of thirty-eight patients, twenty-seven showed either defective resonances, at times amounting to dullness, at one or both apices; which would be sufficient to suggest tuberculosis had there been no other explanation for this abnormality. Twenty-two cases showed either small crepitant or subcrepitant rales, or some sibilation. Five of these thirty-eight patients gave a history of bloody sputum, and one stated that he had had a profuse hemorrhage. During a short service of two months in the female ward of Lebanon Hospital I met with two cases of mirital stenosis showing pathognomonic signs of tuberculous involvement of the apex. One of these patients had even been admitted to a sanatorium, from which she was discharged in six weeks as nontuberculous, and now there was again presented the problem as to whether or not we were dealing with a case of mirital stenosis complicated by pulmonary tuberculosis. Repeated examination of the sputum gave a negative result. In spite of the fact that there was a continued subfebrile temperature, I was not inclined to consider this case tuberculous. A similar case in an adult male was believed to be tuberculous by the attending physician because of the apical signs, yet no tubercle bacilli could be found in the sputum, and the patient kept on gaining in weight and strength after a rest and the use of digitalis. In children also I have often met with cases of mirital disease showing signs simulating apical infiltration, yet the subsequent course of the affection showed conclusively that we were dealing with congestion due to faulty circulation, and not with tuberculosis.

Résumé. Unilateral apical signs which simulate those characteristic of pulmonary tuberculosis are not as rare as is generally supposed. In mouth breathers we often find retraction of the right apex, dullness, altered breath sounds, and even râles which are circumscribed and localized, giving a clinical picture of pulmonary tuberculosis; and the patient is often treated for a considerable time as being tuberculous. These patients are often admitted to sanatoriums, and they are also responsible for the fact that so many methods of treatment and drugs have had the reputation of curing tuberculosis, "when the disease is recognized in its incipiency." Many of the rapidly cured incipient cases are, in fact, instances of collapse atelectasis of the apical par enchyma due to interference with the entrance of air into the right apex in mouth breathers. Individuals who neglect the nasal obstruction for a considerable time, and do not have their polypi, adenoids, or hypertrophied tonsils, etc., removed, may ultimately get collapse induration of the right pulmonary apex, which remains permanent, and thus be in constant danger of being pronounced tuberculous when their health deteriorates from any cause and they are losing weight, have cough, etc.; or, even when feeling in excellent condition, they are liable to suffer unjust discrimination at the hands of examiners for life insurance companies.

But a careful study of the history, symptomatology, and course of this affection obviates such a mistake. Collapse atelectasis and induration are to be borne in mind in all right sided lesions of the lung apex occurring in mouth breathers, showing no tubercle bacilli in the sputum, and manifesting no tendency to follow the usual course of pulmonary tuberculosis, with fever, night sweats, tachycardia, malaise, languor, progressive loss of weight, etc. In such cases the fact that the patient has been working all along in spite of his cough, which may date back to childhood, and has developed physically at a normal rate, speaks very strongly against tuberculosis, and the apical signs are indicative of collapse induration. Physical signs of a lesion at one apex occurring after an attack of influenza, or met with in persons with pulmonary emphysema or defective muscular development, especially in young women, and among indoor workers generally, should not be hastily pronounced as indicative of tuberculosis. It must always be borne in mind that a person who never coughs and has suffered no progressive loss of weight, anorexia, malaise, etc., for months before the onset of an attack of "grippe," may have a simple localized apical catarh giving signs simulating those of incipient pulmonary tuberculosis, although it is not due to acid fast bacilli. On the other hand, the vast majority of cases of tuberculosis give a history of several attacks of "grippe," or "colds," extending over several months or years preceding the last "cold," which, in their opinion, was the beginning of their present illness. Clinical observation for a few weeks, with the judicious use of the thermometer and several examinations of the sputum, usually clears up the diagnosis even in cases in which the physical signs persist for months. In persons having a defect of the mitral valve a diagnosis of
tuberculosis should not be made without the most valid evidence, i.e., positive bacteriological findings. Although mitral stenosis is not an absolute bar to ptosis, as some have maintained, it is exceedingly rare to find this disease complicated by tuberculosis. To diagnosticate tuberculosis in persons suffering from mitral stenosis without acid fast bacilli in the sputum is rather risky. Still, there are often met cases of mitral stenosis presenting symptoms and signs of tuberculosis of the lungs—subfebrile temperature, cough, hemoptysis, tachycardia, loss of weight, dullness, altered breath sounds, râles, etc., localized at one apex—to a perplexing degree. Indeed, I may say that the apical signs in some cases of heart disease have given me much more concern at times than any other class of nontuberculous apical lesions. Often only careful observation for a long period of time will determine whether a given case of mitral disease is complicated by pulmonary tuberculosis or not. My rule has been to consider such cases tuberculous only when finding bacilli in the sputum or signs of cavities on physical exploration.

1337 Madison Avenue.

THE EARLY DIAGNOSIS OF RENAL TUBERCULOSIS.*

BY R. C. BRYAN, M. D.,
Richmond, Va.

Having had the opportunity during the past few years to observe several cases of renal tuberculosis, and having been attracted particularly by the varying clinical manifestations which they have shown, and the extreme difficulty of getting at any satisfactory and definite diagnostic conclusions, I thought it would not be out of place, or uninformative, for me to present to you the pitfalls, errors, and elusive symptoms which this not uncommon and so manifestly latent disease has presented to me personally in the earliest stages of its course.

That renal tuberculosis is a frequently overlooked condition is shown by the records of Kapsammer at the Vienna General Hospital. He reports that from 1897 to 1907 there were found on post mortem examination 191 cases; of these only two were correctly diagnosticated and four partially so, while in 185, sixty-seven of which were unilateral, the disease was not suspected. The writer will not attempt to consider in detail the pathology, predisposing causes, treatment, and other conclusions of the tuberculous kidney, nor the scrofulous kidney which is secondary to infectious diseases, stone, pyonephrosis, floating kidney, or those conditions in which there is an interference with the urinary outflow, but would ask to call your attention particularly to the diagnosis of primary kidney tuberculosis; trying to unravel, in some kind of fashion, the clinical manifestations only in the very incipiency of the disease, and not in the terminal state of casesation of the organ, in which the ureter and bladder are also most seriously involved. Kronlein states that 20.8 per cent. of all surgical affections of the kidney are tuberculous. Israel states that one third of all purulent processes which may be traced to the kidney are of this character. It may not be irrelevant here to say that by a large number of investigators the tubercle bacillus is found in only fifty per cent. of all cases. This includes not only the incipient, early, solitary, military type, but likewise those instances where large caseating foci and marked involvement of the ureter and bladder are also found. Were we able to find the tubercle bacilli earlier, the diagnosis would naturally be much easier. Steinthale asserts that fifty per cent. of all cases of renal tuberculosis are limited to one kidney, while James Israel goes so far as to say that eighty-eight per cent. of all renal tuberculosis is unilateral. This would seem to substantiate the contention of those authors who say that all tuberculosis of the kidney is of a hematogenous origin, and to discredit the transmission of infection by the ascending route. It is in males, in the second and third decade, that the disease is most commonly encountered. Collinet states that one out of every eighteen consumptives suffers from some form of genitourinary tuberculosis. He also affirms that the tuberculous process may start anywhere in the urogenital tract independent of a pulmonary or general tuberculosis. It has been pretty well substantiated that the kidney may become infected from the blood without an established tuberculosis being found in any other part of the body. It has also been pointed out that the blood infects the kidney as a secondary expression in tuberculosis of the lungs or any other organ, and further that the kidney may be involved by continuity of surfaces in ascending tuberculosis from the genital organs below. In this latter instance there must be a fibrotic degeneration of the ureteral os in order to permit of regurgitation, and since this is uniformly bilateral, hematogenous infection would seem to be still further established as the recognized means of kidney infection.

Tuffier subdivides tuberculous invasion of the kidney into some six or seven categories. Duret gives about the same classification, and calls attention to the cavernous type, with single or multiple cavities, and also to that condition of the fatty capsule (adipose scerosis) which at times renders it so hypertrophic as to burst through the kidney into the pelvis, thus blocking it effectually. Senn classifies involvement of the kidney by tuberculosis as 1, mililiary tuberculosis; 2, caseous nephritis; 3, tuberculous pyelonephritis. This is a classification which covers the different pathological findings which develop in the course of the disease. Our consideration, however, will be limited to the first division, our intention being to ignore the diagnosis of strumous kidney with which there are associated distinct tuberculous lesions; for, with a constitutional invasion by the disease, with the large renal tumor, the ureter, bladder, and urethra seriously invaded, numerous tubercle bacilli in the urine, and marked dysuria, hematuria, and pain, the positive diagnosis ought not to be in doubt. Since it is essential for our interpretation and diagnosis of the obscure clinical signs of this primary military condition to have a familiarity with the pathological state which has given rise to this mor-
bid expression, a hasty review of the military kidney will not be out of place. For it is in just this form of renal tuberculosis, the incipient, military type, in which there are only a few minute foci scattered here and there in the cortex of the organ, that the diagnosis is most difficult. These foci uniformly start subcapsularly and in the cortex of the organ. They are implanted here by the blood current of the kidney, which, entering at right angles to the pelvis, flows to the cortex, where its vertical twigs are given off; the centrifugal action of the blood current swirling the tubercle bacilli out to the furthest periphery of the organ. In this stage of tuberculous invasion the urine is negative, but it is now that the toxines cause the dysuria which we find so constantly present in the early stage of the disease. Soon there follows the replacement of the foci by fibrous tissue, and then there ensues polyuria, which, we have noted, seems to be one of the significant features of the disease.

With a mixed infection occurring, these small nodules swell and discharge their product into the pelvis, or, occasionally, the capsule is broken through and a perinephritic abscess is established. Neither this condition nor the invasion of the pelvis will, however, be taken up, as they belong to the second or more advanced stage of strumous kidney. We might take this opportunity to refer to the lymphatic supply of the primary tract and say that the drainage of the epididymis is different from that of the testicle, which flows into the retroperitoneal glands about the sacrum. The epididymal chain runs to the floor of the bladder, where its drainage unites with the mural lymphatic drainage from the kidney about the ureteral mouth. It would not be extraordinary, then, to note a case in which one of the primary evidences of a cortical tuberculosis would be the establishment of a focus by means of this lymphatic stream in the epididymis. The writer had, on one occasion, such a case under his observation. Nor will we overlook the possibility of this lymphogenous infection occurring in the opposite kidney by way of the flow across the lumbar vertebra or by means of the small veins which ply between the kidneys.

In the very earliest stages of implantation there is no urinary complication, but soon we are at a loss to know why a frequency of urination should occur, particularly since the uranalysis and the microscopic and x ray examinations have on repeated occasions been negative in their results. With the establishment of a new focus or the slight spreading of one of the former foci, the kidney becomes more congested, and a permanent polyuria ensues. Now and then some of the products of this invasion, dammed back in the organ, escapes, and the character of the urine is temporarily changed. This polyuria is the result of the stimulation of the glandular tissue caused by the presence of military nodules which have not developed so far as to compromise the parenchyma of the organ. It is, indeed, an irregularly scattered interstitial nephritis of one or several parts of the kidney, and it is at this time that traces of albumin and pus and a few red blood corpuscles may be detected in the urine which not infrequently comes, by virtue of a renorenal reflex, from the unafflicted side. The slight dysuria at the time of these outbreaks is doubtless caused by the liberated toxines irritating the mucosa. This, at least, would appear to be the explanation, and the frequency of urination simply Nature’s method to throw off injurious products. Many patients have found that drinking large quantities of water helps the pain. This may be explained by the dilution of the irritating elements of the toxines which the ingestion of water causes. As an illustration of this early type of case, the writer would record the following:

Case I. Mrs. J. B. L., aged thirty-eight years, referred by Dr. E. W. Gee, of Richmond, had for several years had an annoying and intermittent frequency of urination, attended with considerable pain at times. This pain was low down on the right side, in the region of the pelvic course of the ureter. She had been operated upon for appendicitis with no relief. When seen by the writer the patient, weighing about 180 pounds and with good spirits and color, presented every appearance of enjoying the very best of health. Bimanual examination showed a very markedly retroflexed and retroverted uterus. Repeated uranyses, cystoscopy, catheterism of the ureters, pyelography, and radioscopy (for stone) were all negative. After careful consideration of her condition, it was traced to the door of the retroflexed uterus, which had produced a slight degree of cystocele, and, since the chilametric had been passed, and in the absence of all urinal findings, hysterectomy was advised. Operation was performed March 21, 1912. She remained in the hospital about four weeks, and was seemingly benefited. A few weeks later the frequent and painful urination developed again, so that catheterism of the ureters was once more carried out. On July 17, 1912, Dr. E. G. Hopkins, of the University College of Medicine, Richmond, reported, “Tubercle bacilli present in the urine from the left side, none found in urine from the right kidney.” August 2nd the findings were the same as July 17th, with a small amount of pus and a few tubercle bacilli were found to be present; November 18th tubercle bacilli present in specimen from left kidney.

It is interesting to note that the tubercle bacilli were found only on the sixth or seventh investigation, no suspicion of a tuberculous condition having been previously aroused; and, further, that during the entire course of the disease the pain and distress had been regularly referred to the right side, while the lesion was on the left. This woman is now undergoing tuberculin treatment and seems to be improving daily.

Case II. J. W. D., thirty-eight years old, male, for several years had been having periodic and irregular attacks of frequent and painful urination, for which he consulted a considerable number of physicians who had prescribed varying treatments. December 24, 1911, a cystoscopic examination was made, and a slight trigonal injury was observed. Although there was a slight sacculation of the capacity of the bladder was twenty ounces. The prostate and seminal vesicles were stripped and subjected to microscopic examination, but nothing unusual was found. For the past few months he had been urinating on the average every two hours, day and night. There were periods of relief, which were usually of short duration—a day or so. He found that drinking large quantities of water helped the pain, but this doubtless aggravated the pollakuria. Examination of the urine revealed a specific gravity of 1.000, and neutral in reaction. It contained occasional pus corpuscles and a few small and round reniform cells, but no casts. Catheterism of the ureters showed the urine practically identical on both sides and bilateral hydropsyphrosis of the kidneys to be normal. The patient lived in their proper beds. X ray was negative. May 11, 1912. Patient returning for further investigation of his case, still complained of vesical discomfort and constant pain about the left kidney which was usually worse at night, and although the frequency of urination was not so great as a few months ago, there were considerable embarrassment and inability
to attend to work in consequence of this nagging pain and frequent desire. His appetite was good; his bowels were kept in regular action; and he did not sleep much, if at all, previously. Cystoscopy, catheterism of the ureters, and x-ray examination were again negative; rectal and urethral investigation gave no clue to his trouble. The urine continued of a low specific gravity and was acid, but was otherwise of a negative character. A spray of smoke was inhaled, and it was found that miliary tuberculosis of the left kidney was suspected, and a rigid examination instituted to find tubercle bacilli. The polyuria, which would seem to be significant in this case, is best explained not only by a slight nephritis accompanying the triscystitis in which there is also in the bladder, or by a greater or less involvement of the pelvis of the organ or the ureter, with partial retention of urine in the pelvis of the kidney; a condition which would naturally lead to a pressure atrophy of the tubules in the pyramid, and thus influence the water absorbing power of the kidney. The retention of the urine in the kidney pelvis could also be caused by the fact that so great a frequency of micturition must mechanically interfere with the normal rhythmic contraction of the ureter. It is just such cases as this, with that indefinite, obscure, and indirect train of symptoms, which should put the surgeon on the alert, so as to follow every clue to the possible diagnosis and so avoid the fatal mistake of inattention in termination. The condition of affairs was explained to the patient and an exploratory nephrectomy advised. The kidney was found somewhat enlarged and mottled, but no foe were discovered. A peculiar thickening of the upper pole of the kidney was noticed. Dr. S. B. Moon, pathologist to Grace Hospital, Richmond, gave the following report from the examination of a small section: "About half the kidney tissue is mottled in appearance. Here and there are congested vessels. A large number of tubercles are blood and containing many blood cells. The surrounding epithelial cells are largely disintegrated. The protoplasm, however, stains well. Diagnosis, moderate parenchymatous nephritis.

The urine had been mottled and not a drop could be found. It had been blood and water. The operation had been a success. There was no return of the old pain, and the patient appears relieved of his dysuria. Although the findings and the operation would appear to negative tuberculosis, the writer is still of the opinion that a focus somewhere in the left kidney was the cause of the trouble.

CASE III. Mrs. E. C. L., aged twenty-four years, multipara, until recently had always enjoyed the best of health, weighed 170 pounds, and had had no illness since childhood. Family history negative. About two months ago the patient complained of a frequency of micturition in the urine every thirty or forty minutes. She noticed slight blood in the urine at times, and suffered constant pain, which was made worse by the act of micturition. The pain was sometimes in the loin, and at other times in the region, perhaps a little more on the left side than on the right, and also marked tenesmus. The condition came on gradually and insidiously, and she at length consulted Dr. Howard Armstrong, of Edom, Va., who referred her to the Hospital.

In vaginal examination considerable tenderness was found about the trigone of the bladder. The capacity of the bladder was two and one half ounces; uranalysis showed albumin; no casts; occasional blood cells; a few large, round, squamous epithelial cells; no crystals; a large quantity of pus. There was no pain posteriorly or along the course of the ureter, nor was the abdominal wall anterior to the kidney rigid. Cystoscopy, which was very painful, showed marked edema and inflammation about the bladder and particularly of the left ureteral orifice of the left ureteral orifice, the congestion being so great that the ureteral orifice could not be located for catheterism. By vaginal examination a positive pulsation was felt in the left fornix, and a calculus was noted. There was an extending ulcer, which was taken to be the left ureter, and with it the calculus. With the x-ray examination negative for stone, a provisional diagnosis of tuberculosis was made, and daily examinations were made of the urine for tubercle bacilli. Numerous other bacilli were observed, and especially the colon bacilli and its analogues, but only on the twelfth examination of the urine was the bacillus bacillus in large numbers found. This confirmed the diagnosis and the irrigations and instillations which had been energetically carried on were stopped, and appropriate treatment directed toward the kidney proper. Lumbar urteronephrectomy was performed. The capsule of the kidney was studded with minute foci, particularly about the poles anteriorly. One or two had burst quite freely, and the urine was cloudy and hemorrhagic. At the point of operation, the large number of fibrous tissue, the kidney was mottled in appearance, and irregular areas of fibrosis were noticed in the cortex. There was one cavity about the size of a hazel nut in the upper pole, the walls of which were smooth and hard. The ureter was considerably involved in its upper segment, and after a swabbing out with pure carbolic acid it was tied off as low as possible. On the third day marked improvement was apparent, the frequency of urination being considerably diminished, and the pain not so severe. Already the remaining kidney secreted forty ounces in the twenty-four hours. No tubercle bacilli had been found in the urine since the second day following the operation, and the course of convalescence so far had been uneventful and most happy. At the time of the writing, one month after operation, the patient is up and about and seems to be going on to a satisfactory recovery.

The narration of these three cases, selected from a series, is designed to emphasize particularly the cardinal features of diagnosis of early renal tuberculosis. In our series we find first, that there are no pathognomonic evidences of the early stages of the disease; second, the distressing vesical disturbances would appear to be the leading clue to the diagnosis; third, the repeated negative examinations for tubercle bacilli, in one instance twelve such being made before the germ was found; fourth, the absence of marked papillary hemorrhage, which is accorded a prominent diagnostic symptom, but which pathologically cannot be identified with the cortical invasion; fifth, the stormy and febrile reaction following nephrectomy, with the liberation of a large number of toxic substances and endotoxins into the surrounding tissues. The physical evidences in the early stages of renal tuberculosis are most indefinite and obscure. The patient has at irregular intervals a distressing and annoying frequency of urination, which is more evident by night and continues for an irregular period of time—days or weeks. During the height of the attack there may be some slight tenderness over the kidney, with a slight rigidity of the abdominal wall anteriorly. On the left side an old varicocele may become congested, giving rise to some discomfort. Rectal palpation should always be carried out. At best the findings and chain of evidence are most unsatisfactory, and we must rely in our diagnosis of this condition upon 1, uranalysis, 2, the microscope, 3, the cystoscope, with ureteral catheterism, 4, tuberculin and its allies, 5, kidney efficiency.

The uranalysis in inceptive miliary tuberculosis is inconsistent in the character of its results, for tubercle bacilli are not always implanted upon an absolutely normal kidney. The urinary findings, then, may show evidences of a nephritis of more or less severity, and, in fact, the laboratory returns constantly report the condition present as Bright's disease of varying degrees, for in this early stage the urine is that of a renal congestion. The specific gravity, on account of the renal stimulation and water drinking, and because of the irregular thickening of the capsule producing a patchy interstitial nephritis, is low. Later on, with cellular elements coming away and the kidney not responding so promptly to the toxic stimulus, it is considerably higher. It is, however, seldom as high as in the normal state. The reaction of the urine is one of the most notable features of the strumous kidney; this is regularly and constantly. Pus is one
of the characteristic indices of the invasion of the tubercle bacilli, and its production represents nature's attempt to prevent the spread of infection. Although the pus is not constant, but intermittent, a few cells in a regularly acid urine would at least give us a clue for diagnosis if we were satisfied as to the absence of stone. Pus in a constantly acid urine would appear to be the password for early renal tuberculosis. Blood is found in the urine from time to time, and, with the implantation of the process on the tip of a papilla, there may be some hemorrhage. The bleeding may be so free as to cause a blocking of the ureter by the inspissation of the débris from above, resulting in an embarrassing train of disagreeable symptoms, a veritable Dietl's crisis. This papillary tuberculosis is rare, but occasionally the large loss of blood, with all other findings negative, gives a clue to the possible diagnosis. Albumin may or may not be present. With a considerable amount of epithelium the test will be positive; protoplasma and serum albumin must therefore be differentiated. The albuminuria of the ordinary tuberculous patient is bilateral, while that of a renal tuberculosis is unilateral. The character of the epithelium present represents the location of the morbid process. Urine acid crystals are frequently present as the result of the constantly acid urine. Casts, hyaline, granular, and epithelial, may be found in the urine as the result of the tuberculous invasion; which would appear to be the kidney's response to the toxic irritant, and not as a phenomenon of acute circumscribed nephritis. Hunner reports casts present in ten per cent. of his cases. Morris asserts that polyuria (the thalurias of Tildon Brown) in a frail patient of tuberculous family, for which no other cause is assignable, should excite suspicion of renal tuberculosis. This pollikariuria is peculiarly nocturnal, and not relatively so marked during the day.

In the microscopical examination the smegma bacillus and acidfast streptothrix must be differentiated from the tubercle bacillus. The writer would recommend that all the urine voided be carefully collected with the strictest precautions, preferably in a Stenbeck's sedimentator, preserving it with boric acid, one grain to the ounce of urine, and that the best expert obtainable be employed to investigate it for the tubercle bacilli. It may require a week or more for a result in any way positive. Even then a negative bacteriological examination does not disprove the clinical diagnosis; for, with only a few cortical spots well surrounded with unyielding fibrous tissue, the extreme difficulty of securing, segregating, and recognizing the offending tubercle bacillus must be at once evident. It is sometimes surprising how examinations for a week or more give no evidences of the tubercle bacillus; yet then suddenly a large number will be found to have come away. This condition of affairs has obtained in several of our cases (see Case III). It would appear that the multiplication and evacuation en masse of the bacilli would be of less damage to the urogenital mucosa than if a constant stream of less numbers were to be always present. The urgent importance of repeated examinations cannot be too strongly emphasized.

As to cystoscopy, in the very early stages nothing may be noted about the patient's bladder or ureteral orifice. Soon, however, with the more marked invasion of the kidney proper, there is a flushingness, blueness, and injection of the ureteral opening which is consequent upon a fibrotic formation and retraction (Fenwick's golf hole orifice). Only recently Buergner has called attention to an "edema bullosum" of the ureteral os which is present even when the ureter is not involved. He considers this the most distinctive initial feature in the diagnosis of early renal tuberculosis. In the second and third stages of the disease well defined tuberculous ulcers are seen about the trigone and ureteral mouths. Catheterism of the ureters is here a tedious and difficult procedure. Ureteral spasm is easily provoked, and bitting of the catheter ensues, which causes a considerable amount of pain and discomfort. Radioscopy may be used for differential purposes, but not with much hope of its confirming a possible diagnosis. Pyelography would not seem to be of any material benefit in the diagnosis. The tuberculin or T. R. test, von Pirquet's reaction of the skin, and Calmette's reaction of the conjunctive may be used as corroborative measures. These latter tests are to be more or less condemned or at least conducted with great caution, as they are dangerous procedures on account of the marked edema of the ureteral mouths which have been noted—in certain instances producing fatal suppression. Injections of the sediment into the peritoneal cavity of the guinea pig would appear to be an efficient diagnostic measure. Culture processes may be tried also. The renal efficiency may be investigated by one of the following means: Cryoscopy, the freezing point of the blood and urine; the chromocystoscopy of Völcker and Joseph with indigo carmin; phosphorizing, producing a temporary glycosuria; Morro's test, particularly good in the case of children; Wright and Killmer's method of hemolysis; the determination of urea secretion as perfected by Rovsing; and finally the phenolsulphonphthalein test, which the writer highly commends as the best means for ascertaining unilateral efficiency, consequent fibrotic replacement, and renal degeneration. It must be borne in mind that the kidney, like other organs, may suffer a pathological invasion and still possess sufficient resistance to ultimately attain a remitto ad integra. The adjustment of the actual kidney condition and the pathological findings to what we hope to get by uranalysis and microscopical and other investigations cannot always be so arranged as to be simultaneous and complementary. Although spontaneous cure of tuberculosis of the kidney is unknown and the disease usually progresses per saltum, it might be possible to imagine a discreet military focus which had given rise to considerable embarrassment and yet on investigation yielding no definite findings to justify a positive diagnosis. The focus has healed, and patches of irregularly scattered fibrous tissue, here and there, just under the capsule and burrowing but a short way into the cortex, are the only remaining evidences of the former tuberculous invasion.

A hasty review of the foregoing signs would lead us to attach particular significance to the subjective complaints of dysuria and pollikariuria. For these would appear to be the constant and cardinal symp-
toms given by the patient in his distress. Objectively there are no physical findings of value in the early stages of cortical tuberculosis. The questionable rigidity in the abdomen anteriorly, or the tender spots posteriorly, cannot at all times be elicited. The general practitioner must confuse his energies toward the investigation of the urine, the significant features of which are a constant acidity and intermittent pyuria, for it must rest with the expert microscopist to differentiate the renal morphology and stain for the germ of tuberculosis. Cystoscopy and the tests for renal efficiency should be placed in the hands of one peculiarly skilled along this line. Too much importance cannot be attached to these two means of diagnosis. At best, however, all our investigations and clues are hazy and indecisive, so that it is by a combination of agencies rather than a single one, that we are made acquainted with the pathological processes which in the large majority of cases is constantly progressing unfavorably.

There are many of us who doubtless during our professional lives have witnessed a considerable number of cases which have been characterized by a frequent and painful urination and in whom the findings have been repeatedly negative. Could not this condition be put at the door of a renal tuberculosis of limited extent which ultimately became absorbed or replaced by connective tissue? The writer is of the opinion that the strumous kidney occurs more frequently than is generally believed, and in the absence of stone, tumors, floating kidney, and diseases of the kidney and pelvis proper, that an earnest and repeated investigation of the physical findings and urine will on certain occasions be rewarded by the establishment of a tuberculous trouble. It would appear, then, that reduced to its final analysis, the diagnosis of renal tuberculosis is actually one of exclusion rather than substantiation. In conclusion, we would recommend the less radical means for treatment in the early stages, such as tuberculin and dietetic and hygienic measures. During its entire course the physical condition and the urine must be investigated most carefully and thoroughly. Any evidence of progressive invasion should be interrupted by immediate nephrectomy or nephroureterectomy, provided the kidney of the opposite side has been tested as to its capacity. It would seem, from a review of the cases which have fallen under the observation of the writer, that nephrectomy is preferable. We cannot, however, believe that such heroic measures should be adopted in any instance without proper investigation directed along the most scientific and deliberate lines.

301 West Grace Street,

THE LUTIN SKIN REACTION IN SYPHILIS.

By David J. Kaliski, M.D.,
New York.

From the Pathological Laboratory of the Mount Sinai Hospital.

Great progress has been made during the past decade in the diagnosis and treatment of syphilis. The impetus given by the discovery of the Spirocheta pallida and of the application of the Bordet-Gengou phenomenon of complement fixation to the diagnosis of luetic conditions has resulted in the accumulation of a mass of scientific data, making possible the application of the newer chemotherapeutical principles in a practical, as well as scientific manner.

However, in spite of great strides forward, the detection of syphilis by means of laboratory aids has not been perfected to such an extent that additional help would be superfluous. While the means at our command are on the whole quite satisfactory, they occasionally fail in the detection of conditions which, etiologically and clinically, are syphilitic or the result of previously existing active syphilis. Therefore the recent endeavors of workers to cultivate the Spirocheta pallida in pure culture have been of interest in view of the possibility of applying cutaneous tests analogous to the well-known skin reaction of von Pirquet in tuberculosis. The scientific labors of Noguchi in the field of syphilis research have been productive of remarkably fruitful results. He has, for the first time, cultivated the spirochete, or Treponema pallida, in pure culture, differentiating it morphologically, as well as culturally, from similar organisms. He has infected laboratory animals with these cultures and has been able to recover the spirochete from the tissues and fluids of the infected animals. He has also proved, by means of biological tests the presence of the infection in the blood of the animals experimented upon. And now, as a result of this work, he has devised a means of applying a suspension of a number of strains of the killed cultures of the spirochete locally by intradermal injection. This test is based upon the fact that animals suffering with a chronic infective condition enter into a state of altered reactivity or allergy. Individuals sensitized or made allergic by passing through certain infectious diseases, or still harboring the organisms of such disease, react peculiarly when vaccinated with a concentrated culture of the organisms or with the extract of the tissues or organisms of the infective process. In this respect the person injected behaves analogously to certain animals reinjected after an interval following sensitization with a foreign protein.

Numerous methods of cutaneous and subcutaneous vaccination in syphilis have been tried, but up to the present time none has proved of any definite value. The results have hardly been either specific or of sufficient constancy to be depended upon. A recent repetition of most of the methods tried up to date by Fantona proved that the results do not approach those obtained by the use of the Wassermann test. They were not of sufficient constancy or specificity in syphilis to give any of them a place in our clinical armamentarium. It is of interest, therefore, to inquire into the merits of the reagent prepared by Noguchi for intradermal injection. The first material used con-
tained two strains of the Treponema pallida. The reagent was first injected into rabbits infected with syphilis, and later human beings were injected. The appended table gives the results of the first 315

| TABLE I.—LUETIN REACTION IN VARIOUS SYPHILITIC CONDITIONS AND IN CONTROLS. |
|---|---|---|---|---|---|---|---|---|

cases injected by Noguchi. There were 250 normal controls, none of which reacted positively. The luetin prepared recently has had incorporated in it six or seven strains of the Treponema pallida. There have been a number of confirmatory reports by clinicians using the material prepared by Noguchi. Owing to the great difficulty of isolating the Treponema pallida in pure culture and growing the organisms in any abundance, all the reports that have been published up to date, including the author’s, have been the result of the injections of the reagent (called luetin), prepared by Noguchi.

The luetin is prepared as follows: The organisms obtained originally from chancres, condylomata, etc., are grown in ascitic agar and ascitic broth containing sterile tissue, usually placenta or kidney. The cultures are grown anaerobically in the thermo-

strains of the pallida as available, and as free as possible from irritating culture medium and preserving. Up to the present time the great difficulty of obtaining the organisms free from the medium in which they grow has in all probability been a factor in the number of nonspecific reactions obtained. It is essential to dilute the concentrated luetin sufficiently to prevent a local irritative reaction. Thus, each new preparation of luetin should be tested on a number of normal controls to determine its irritative properties before suspected cases are subjected to the test.

The reagent is injected into the superficial layer of the skin with a very fine and smooth hypodermic needle until a small, pale wheel is produced. About 0.05 c. c. to 0.07 c. c. are usually injected. The flexor surface of the forearm or the outer side of the upper arm may be used for the injection. I have been in the habit of using the left forearm for the luetin injection and the right forearm for the control. According to the published reports of Noguchi and others, there is either no reaction at all at the site of injection in normal individuals or a small erythematous area which recedes within forty-eight hours. After observing the reaction to the injection in a large number of apparently normal individuals I have come to the conclusion that with the present method of preparation of the luetin there occasionally develops at the site of the injection of the reagent, and also at the site of the control injection, a small area of infiltration varying in size up to about eight or ten millimetres, which is often surrounded by a bluish erythema and which may persist for from two to four days.
There is usually no marked infiltration present. The occurrence of this type of reaction has been of sufficient frequency to lead me to disregard what Noguchi calls the "papular" reaction as a specific phenomenon, unless the area is greater than eight or ten millimetres in diameter and is markedly infiltrated. The reaction that I have learned to consider positive is a markedly infiltrated papule over eight millimetres in diameter, which persists after the third or fourth day as such or progresses to definite softening or pustule formation. The inflammatory area may be capped by a few small vesicles, which may rupture or become filled with pus. The pustule may begin to form after the second or third day in severe reactions and increase in size until it reaches the size of a plum. It may rupture spontaneously or become absorbed; in the latter event the site of injection may remain infiltrated and pigmented for a month or more. The severe reactions are occasionally accompanied by intense itching and burning in the armpit, but I have failed to observe general symptoms attributable to the local lesion. In only a few instances have the axillary nodes been slightly enlarged.

It is usual for the reaction in positive cases to begin to disappear about the sixth or seventh day, but in some cases the local lesion may remain infiltrated for a longer time and pigmentation may persist for many weeks, or even a few months, after inoculation. There is a torpid or tardy form of reaction which has been observed in a small number of cases, usually of cerebrospinal lues or tabes. At the end of the usual period of observation the reaction appears to be negative, but about the seventh or tenth day a small vesicle or pustule appears at the site of inoculation of the luetic. This lesion is usually about one centimetre in size and may rupture and discharge a small amount of serosanguineous material (hemorrhagic reaction) or go on to the development of a small pustule. In a very few cases I have observed, only at the site of the control injection, a definite reaction, similar in all respects to the positive papular or pustular reaction. These cases were in normal individuals. Similar specimens of control injection fluid in other individuals failed to cause any reaction whatever. I have no explanation to offer for this paradoxical reaction other than the possible presence of irritative factors in the control material or local skin susceptibility to infection.

In about ten per cent. of all active syphilisics who reacted positively to the luetic test there was a reaction of equal intensity at the site of the control injection. In a few instances the control injection reacted even more markedly than the luetic site. This peculiar phenomenon may be explained as follows: It is a well known fact that the skin of syphilisics is susceptible to trauma, and that not infrequently gummata form at the site of such injury. Finger was of the opinion that at such a place a locus resistantiae minoris is formed, into which the virus or organisms of the disease wander and cause a lesion. This is the theory of superinfection. Neisser, since he could never find the organisms in these lesions, denied this hypothesis and maintained that there was an altered condition of the skin itself responsible for the pathological condition. This condition of the skin Neisser called Umstellung. It is this explanation that Noguchi offers for the occurrence of reactions at the site of the control injections in cases of syphilis.

Marked Umstellung was observed in a number of tertiary cases and in one of the hereditary cases. Further, a few cases in which I have been unable to discover any specific taint (the history, clinical course of the disease, and the Wassermann reaction all being negative) gave definite Umstellung. Inasmuch as all the cases were injected in series, the reaction at the control site could not be attributed to too great concentration of the luetic. The reagent was always sterile when injected. Of course, we must always bear in mind the possibility of infection by skin bacteria of an area rendered somewhat susceptible by the injection of a slightly irritating reagent.

This paper is the result of experience gained by the injection of nearly four hundred cases of syphilis and nonsyphilitic conditions.

PRIMARY AND SECONDARY SYPHILIS.

In primary and secondary syphilis the proportion of positive results is so small as to render the test of little practical value. In thirty cases, in most of which there were active lesions, the reaction was definitely positive in three cases (ten per cent.). Some of the patients were injected before and some after treatment. The Wassermann reaction in these cases, treated and untreated, averaged eighty per cent. of positive results. In one of the cases, in which the luetic reaction was positive after the patient had received salvarsan and mercury, the Wassermann reaction became negative and remained so. No definite relationship could be noted between the amount of treatment and the outcome of the test in this stage of the disease. It would appear that in the active stages of syphilis, when the tissues are invaded by the organisms, the body has not entered into a condition of altered reactivity or allergy.

TERTIARY SYPHILIS.

It is in the tertiary stage of the disease that the test seems to have its widest and most useful application. A few published reports by observers have shown a very high proportion of positive results in tertiary syphilis. My figures are not quite so high. In thirty cases of tertiary lues I have obtained positive luetic reactions in nineteen (sixty-three and one third per cent.). In a number of the test was positive in twenty-three of these cases (seventy-seven per cent.). In a number of the patients the Wassermann test was positive, although they were under very active treatment. Two cases gave both a negative luetic and Wassermann reaction, one being that of a patient with malignant lues, the other a tertiary luetic with spinal symptoms. Four cases gave positive luetic reactions and negative Wassermann reactions. One was that of a patient with marked periarthritis and synovitis who recovered after antipsychic treatment. The others were cases of aneurysm of the aorta, myocarditis with tertiary luetic manifestation and cerebral embolitis. In all these instances the diagnosis was established or confirmed by the positive luetic reaction. In a case of spinal tumor both the Was-
sermann test and the luetin reaction were positive. The tumor removed by operation proved to be a glioma. Of course, there is the strong probability here of the existence of a neoplasm in a specific individual. In seven active cases the Wassermann test was positive and the luetin test was negative, while in four cases the luetin test was positive and the Wassermann reaction resulted negatively.

Thus, the reaction was of definite diagnostic value in a number of cases, although the figures were not as high as those obtained by the Wassermann test. It seems that the individual is in a state of allergy in this stage of syphilis, and it is to be hoped that with the further purification of the reagent and the incorporation in it of a larger number of strains of the Treponema pallida, the allergic reaction may be brought out in a larger percentage of the cases.

HEREDITARY SYphilis.

The luetin test was positive in but one case, while the Wassermann test was positive in five cases. Unstimmung was marked in the positive cases. All of these cases were in children over three years of age who had manifest lesions, and but one of them had been treated. Two of these cases gave suspicious reaction to luetin. In four other members of luetic families in which a serum test could not be obtained the luetin tests were negative.

TABES.

In thirty-two cases of tabes in which the Wassermann test was positive in the blood and spinal fluid in about half the cases, the luetin reaction was positive in but three cases. In no case in which the Wassermann test was negative did I obtain a positive luetin reaction. Many of these patients were in the late degenerative stage of the disease, in which all the tests, both of the blood and spinal fluid, were negative. In one of the cases, which also showed lesions of tuberculosis, a tardy pustular reaction with Unstimmung was obtained.

CEREBROSPINAL SYphilis.

The test is of more value in cerebrospinal syphilis. Of thirteen cases, four gave a positive luetin reaction and nine were negative. Thus, in this form of lues, representing a more or less active invasion of the nervous system, the reaction tends to give a larger proportion of positive results. One of the patients were injected three times, and each time a pustular reaction resulted. Two of the cases showed the tardy reaction and one of these gave the tardy reaction twice.

LATENT LUES.

In seven old luetics who had been well treated and had not recently presented lesions, the tests were uniformly negative. In four of these cases the Wassermann test was positive.

CONTROLS.

As to controls, I was able to observe for a sufficiently long time to be able to rule out all latent or delayed reactions—225 cases of the type, one is apt to meet in the wards of a large hospital. It must be taken into consideration that while syphilis is a factor in the lives of the type of patient coming to the Mount Sinai Hospital and the Montefiore Home, this disease is not so frequently met with as in the patients of some other institutions. This is especially true of the older generation of Hebrews. My results show that out of the 225 cases there were twelve definitely positive luetin reactions in cases in which the Wassermann tests and histories were negative. In none of the cases could any evidence of the disease be found intra vitam. (As mentioned above, I have not taken into account small papules at the site of the inoculation, else the number of "nonspecific" results would be greater and, it should also be mentioned, the proportion of positive results would approach the higher figures of other observers.) Each of these twelve cases presented a negative history and repeated Wassermann tests were negative. One was a case of gout, another cirrhosis of the liver and a third nephritis. The two latter occurred in individuals who were fathers of large and healthy families. Three cases of tuberculosis gave definitely positive reactions. In thirty other cases of tuberculosis the test was negative, although I noted a tendency to slight papule formation in many of these patients. A case of myasthenia gravis gave a definitely positive reaction in three times. Blood and spinal fluid yielded a negative result to all tests. A case of multiple sclerosis at the Montefiore Home twice gave a positive reaction. A case of scrofuloderma reacted positively three times. At various institutions this was regarded as a case of tuberculosis. Antispecific treatment was of no therapeutic value, but tuberculin treatment was decidedly beneficial. The three remaining cases were of nephritis, endocarditis, and psoriasis; all without ascertainable specific taint.

That syphilis may be a latent factor in some of these cases is possible, though the usual criteria for determining the condition were absent in all. This leaves us with a small proportion of nonspecific results for which I can offer no explanation. However, I think that in any intradermal reaction the introduction of the reagent under or into the skin is occasionally attended with a certain traumatic risk to the skin, and the presence of skin bacteria must always be a latent factor in causing occasional nonspecific reactions. As I suggested before, a further purification of the luetin will probably reduce the proportion of nonspecific results to a minimum. In this event the reaction will be of exceptional negative value as a routine test for the presence of latent lues. It will require further work, both on the part of investigators trying the reaction upon patients in the wards and dispensary, and on the part of the originator of this new aid to the diagnosis of specific infection, to whom we must look for a more virulent and less irritating product, before the final value of the test will be known and before any comparison with other methods which have been in use for diagnosis for almost a decade can be made.

To summarize, from what has gone before, it is apparent that the test, as now applied and with the luetin now in use, is of little value in the active early stages of syphilis—i. e., in the primary and secondary stages. I have been unable so far to formulate any definite criteria from a prognostic standpoint concerning the value of the reaction in
trated cases of active lues. The leucin test is of little help in so called parasitic conditions, especially the old degenerative types, and I agree with Noguchi that it cannot compare with the Wassermann reaction for diagnosis in such conditions.

In cerebrospinal syphilis, on the other hand, it is of service, and the results in an extended series of cases in the active stages of this disease should approach those obtained in the tertiary period. In the tertiary stage of syphilis the reaction seems to be of the most value and is a valuable supplement and adjunct to the Wassermann test. In a large series of cases the test was specific for lues with the exception of five per cent. of the cases in which syphilis may possibly have been a factor.

I wish to express my sincere thanks to the attending physicians and surgeons of Mount Sinai Hospital for their courtesy in extending the privileges of the wards to me, to Dr. S. Wachsmann, of the Montefiore Home, for similar courtesies, and to Dr. David Beck, of the Mount Sinai Hospital House Staff, and Doctor Palefsky, of the Montefiore Home, for their kind assistance.

THE NEED OF THE MICROSCOPE IN THE TREATMENT OF GONORRHEAL URETHRITIS AND PROSTATITIS.

By Joseph Broadman, M. D.,

New York.

Visiting Urologist, Washington Heights Hospital Dispensary; Assistant Urologist, German Hospital Dispensary.

Most of the textbooks and monographs outline the treatment of gonorrheal urethritis, according to different stages, each to last a certain number of weeks, into which the disease is arbitrarily divided. Each of these stages is supposed to last for "so long," and then another stage is expected to begin, and to be treated accordingly. If these conditions were treated scientifically, and with the aid of the microscope, to actually see the changes that take place in the urethral canal, as shown in the discharge, no such unscientific stages and consequent treatment would be called for, as will be shown later.

Concerning prostatitis, altogether too little is mentioned, and yet the existence of an unseen infection of this gland is the cause for more recurrences of specific and nonspecific urethritis than many are willing to believe. The mere fact that there is enlargement of the prostatic gland, as found by palpation with the finger in the rectum of a young man, is not enough reason to suspect it of carrying infection. Nor is a small prostate always healthy. Even such prostatic glands as feel normal or nearly normal on palpation may be infected, and the only certain way to determine the condition of this gland is to obtain the secretion therefrom for a thorough microscopical examination.

Acute infections of the urethra. We all know that not every discharge from a meatus is of gonorrheal nature, and yet, unless this is properly examined to determine the cause we are apt to treat such cases as gonorrheal infections. Should it happen to be an infection due to some organism other than the gonococcus, appropriate treatment may cure it within a few days, while if such a case is to be treated as gonorrhea without first consulting the microscope, the patient would be much better off if he had not consulted the physician for a few days, because by this time he would probably be well without any treatment at all except the constant flushing of the urethra by the urine.

More frequently than is generally supposed, an acute discharge from the urethral meatus is due to the presence of a chance in the urethral canal. The presence of syphilis as the cause would not even be suspected in most cases if it were not for the fact that upon microscopical examination no gonococci were found in such acute discharge.

If a patient who presents himself for treatment really has a gonorrhreal infection, the diagnosis should be made or confirmed by making a smear of the discharge present and examine with the microscope to determine whether the gonococci are intracellular or extracellular and the portion of the extracellular gonococci with the intracellular ones when both are present. Physicians who treat their patients in this manner know that a great deal of benefit results from these determinations. If all gonococci in a given case are extracellular, such case can sometimes, if not often, be aborted, and the probability of aborting these cases diminishes with the increase of the number of intracellular gonococci. It very often happens that a patient with discharge, and a large number of intracellular and extracellular gonococci, being treated only once at the office, is instructed how to treat himself at home, and returns to the office the next day, not showing a single gonococcus in the smear. In other cases the gonococci may not disappear for two or three days, while in others this may take a week or ten days, or even a longer time. In cases where the gonococci disappear promptly, after appropriate treatment is instituted, and if such treatment is modified according to the microscopical findings as the case progresses, the patients get well in a very short time—certainly much less than the proverbial "six weeks."

But beside having the gonococci and its situation to guide us, if we use the microscope, we have other constituents in the discharge to give us additional information. Thus we find the presence of pus cells, epithelial cells, and mucus, and it is only by a thorough understanding and consideration of the presence of these constituents in greater or lesser quantities or proportions, and an appreciation of the significance of their absence during the course of treatment, that we can treat our patients properly and in accordance with scientific principles. A great many of these infections, especially those which have been treated for some time with some
of the silver salts, show a very profuse purulent discharge, due to overtreatment and consequent irritation, as shown by the microscopical findings, and not a few of such patients are treated even more vigorously because of this very discharge, whereas a proper examination would have indicated the necessity of discontinuing the injections. It is undoubtedly true that to treat a gonorrhoeal infection without the aid of the microscope as a control, is just as reprehensible as it would be to treat typhoid fever without taking the patient’s temperature.

Chronic urethral infections. Chronic infections of the urethra may be due to gonococci, or to some other bacteria. Unless we are quite certain what we are dealing with, how can we give appropriate treatment? It is true that in a small proportion of cases even the microscope is not of sufficient aid; so that we have to resort to cultures to determine the nature of the infection. Chronic infections often require a great deal of instrumentation, and it would be very unwise to introduce instruments of any kind without finding out whether the canal is free from bacteria. The presence of a mucoid secretion, as we find it in such cases, does not necessarily denote the presence of bacteria, nor does the scantiness of a secretion exclude their presence. There are types of bacterial urethritis which, under appropriate treatment, will clear up in a couple of days, some that will take a few days, or even longer for this, and still others that are perhaps incurable. But who can diagnose and treat these without microscopical aid?

The instrumentation essential in the treatment of chronic urethritis often gives rise to an irritative discharge, but since a discharge may also arise from the use of nonsterilized instruments, the only possible way of making a diagnosis of the nonbacterial discharge in the first, and the bacterial one in the second instance, is by means of the microscope. Naturally, the treatment should vary in these different conditions; can this be done without a proper diagnosis?

But few chronic cases of urethritis are due to the presence of gonococci, and it is of great significance when their presence can be demonstrated, because they are very resistant to treatment. Instances where gonococci persist for from four to six weeks, or even longer, in the discharge should not be referred to as chronic unless it is certain that their presence is not due to inappropriate treatment. A discharge does not have to be profuse, or even moderately large, to contain gonococci, and it is very surprising sometimes to find that a very slight, innocent looking mucoid secretion contains them. It is important to examine microscopically the well-known “morning drop” of chronic urethritis, though in most cases only an endoscopic examination will reveal its cause; for often the gonococci will be found in this drop, when during the rest of the day none can be found. On the other hand, the morning drop may be due to diplococci, staphylococci, the micrococcus catarrhalis, or other microbes. We often see instances in which two or three days after sexual intercourse a man has a slight discharge from the urethral meatus which looks purulent and is more profuse in the morning. Such discharges are due to an irritative secretion the female was afflicted with, and on microscopical examination they generally show, beside the other constituents of pus, a large number of other bacteria, but no gonococci. If they are properly diagnosed, from three to five days, or even less time, suffice for a cure.

Acute prostatitis. To treat a case of gonorrhoeal infection, especially one in which the patient does not markedly improve or get well in the first two or three weeks, without making an occasional microscopical examination of the prostatic secretion, is almost equivalent to allowing a prostatitis to progress without treatment. These examinations are very important because, though we may have a prostatitis involvement of severe enough degree not to escape notice, we may also have slight involvements that deceive us for the time being, and later, if wondering why the patient does not get well, we do examine the prostatic secretion, and find that the delay has been due to a prostatitis, which may have steadily grown worse. Even those instances in which the last portion of urine is turbid, denoting a prostatic infection, it would be far more scientific to actually find an increased amount of pus in the prostatic secretion, because, after all, this is not the only condition in which the last portion of urine is turbid.

Gonococci are as apt as not to be found in a gonorrhoeal prostatitis, and their presence is of importance because in such cases are some of the severe complications, such as gonorrhoeal rheumatism, endocarditis, epididymitis, orchitis, etc., prone to develop, and also because in such involvements of the prostate, the treatment would have to be more directly and more vigorously applied to that source.

According to many authorities the treatment of urethritis should be greatly changed as soon as an extension of the infection to the prostate takes place. It would therefore seem necessary to be able to make a positive diagnosis of such extension as early as possible. In prostatic involvements the urine will clear up long before the prostatitis, and if we are to have no microscopical examinations of the secretion, how are we to tell when the process is over? The appearance of the urine and the size of the prostate are entirely untrustworthy as indices. The appropriate treatment at the outset of prostatic infections until microscopically cured would reduce the number of patients suffering from chronic prostatitis very appreciably.

Chronic prostatitis. This includes those slight or moderate infections of the prostate that have been overlooked and also those that became chronic in spite of our best efforts and care. The size of the prostate may be normal or it may be larger or even smaller than normal, and therefore this is of no diagnostic value. To illustrate: A patient came to me who had previously been to a number of physicians who had treated him by copious massage; and I cured him without massage. He complained of a discharge from the urethra recurring at frequent intervals, which was more marked after partaking of alcohol. Upon examination I found him a man of twenty-eight years of age, of large stature and good development. He had a moderately large prostate, and it seemed that every physician he visited took this, evidently on account of its enlarged
size to be the seat of his trouble. When I palpated his prostate, I had the same suspicion, but, upon examination of its secretion with the microscope, found it perfectly normal. Then looking for the seat of trouble elsewhere, and finding it in the anterior urethra, I soon had the patient cured. This case is mentioned merely to show emphatically how important these details are.

In treating chronically infected prostates, we all know that many of them take months to cure; yet, how are we to judge when treatment is no longer necessary? The microscope is the only guide.

510 West 144th Street.

PRIZE ESSAYS.

Questions for discussion in this department are announced at frequent intervals. So far as they have been decided upon, the further questions are as follows:

CXXV.—How do you treat burns? (Closed June 16th.)

CXXXVI.—How do you treat cholera infantum. (Answers due not later than July 15th.)

CXXXVII.—How do you treat threatened abortion? (Answers due not later than August 15th.)

Whoever answers one of these questions in the manner most satisfactory to the editor and his advisers will receive a prize of $25. No importance whatever will be attached to literary style, but the award will be based solely on the value of the substance of the answer. It is requested (but not required) that the answers be short, if practicable no one answer to contain more than six hundred words; and our friends are urged to write on one side of the paper only.

All persons will be entitled to compete for the prize whether subscribers or not. This prize will not be awarded to any one person more than once within one year. Every answer must be accompanied by the writer's full name and address, both of which we must be at liberty to publish. All papers contributed become the property of the Journal. Our readers are asked to suggest topics for discussion.

The prize of $25 for the best essay submitted in answer to Question CXXXIV has been awarded to Dr. John H. Shaw, of Philadelphia, whose article appears below.

PRIZE QUESTION CXXXIV.

THE TREATMENT OF MUSCULAR RHEUMATISM.

By John H. Shaw, M.D.,

The treatment of muscular rheumatism or myalgia depends entirely on the etiological factors and the locality of the affection.

Before taking up the treatment it will be necessary to give briefly a description of the condition usually seen.

Muscular rheumatism is an acute and sometimes chronic affection, characterized by pain, especially on movement, tenderness, spasm, and more or less localization in certain muscle groups. It is usually caused by unaccustomed overuse of certain muscles and may be brought on through exposure to cold and wet. Localized chilling of the body by drafts or sudden change of weather have caused the condition. Some persons have a certain predisposition to the disease. There is usually, however, a history of a sudden exertion followed by severe pain which enables the person sometimes absolutely, lifting weights and indulging in unaccustomed sports are commonly observed. There are certain muscle groups which are particularly prone to suffer: The muscles in the loins and their tendonous attachments, giving the condition commonly called lumbago. Torticollis is a similar affection involving the trapezius and sternocleidomastoid muscles. Pleurodynia is an involvement of the intercostal muscles. The treatment of the condition may be divided into local and internal. A patient suffering with myalgia of the back often demands morphine, as the pain will be unrelieved by other drugs. He must be put to bed and absolute rest enjoined. Catharsis if indicated is necessary, especially if the patient has a tendency to the affection. Salol and acetate of sodium or potassium iodide may be administered if there is special indication.

The diet should be light and liquid principally. The main treatment together with rest in bed is the application of heat (not cold) in the form of fomentations, poultices, and hot water bags. Dry cupping over the region of tenderness one half hour twice or thrice daily is very beneficial. If there is electricity in the patient's home, one or two electric light bulbs placed a half a foot from the body directly over the affected part, a piece of asbestos, tin, or woolen covering encircling, so as to concentrate the heat, will produce a hyperemia, which will greatly facilitate Nature's process. The skin should be protected by anointing with petrolatum; blistering has resulted without its use. The electric light bulb apparatus is, however, more serviceable. This treatment I have found very beneficial, together with light massage, after which a woolen cloth is placed over the hyperemic area.

The galvanic current for five or ten minutes may be applied. Acupuncture has been used, but I have found it not necessary. Turkish baths are very helpful, especially in those predisposed, care being taken against exposure to cold afterward.

Light massage with the use of a suitable lubricant which contains analgesic qualities I have found serviceable. The following I prescribe:

R. Menthol. 11
Camphor. 11
Hydrated chloral. 5s-5i
Oil of gaultheria. 5s-5i
Hydrous wool fat. 5i-5i
M. ft. unguentum.

After the patient is able to be out of bed a suitable adhesive plaster dressing will enable him to walk with slight muscular fixation.

Those who have a tendency to myalgia should be directed to indulge in systematic, but not violent, exercise, to keep the skin open by the weekly or twice weekly Turkish bath. Any tendency to constipation must be corrected by the daily habitual movement without the usual drug addiction. Any tendency to visceroptosis will be helped by exercise or, if marked, a suspensory abdominal binder will relieve.

In torticollis the same measures may be used. If the condition should be of long standing, myotomy may be necessary. Pleurodynia is best treated by hot applications, massage with an analgesic lubricant, and strapping with adhesive plaster.

In summarizing the treatment of muscular rheu-
matism is will be found that the most suitable management of such a condition would be the use of
1. Rest.
2. Hyperemia (dry.
4. Massage, at first light, later by friction.
5. Correction of any tendency to the affection.  
6. Exercise (systematic).
7. Baths.

Dr. Karl A. Meyer, of Hot Lake, Oregon, says:
The treatment of muscular rheumatism is of marked importance to the general practitioner for two reasons: 1. The great number of these cases that come under his observation; and, 2, his inability to secure results in the great majority of cases, these same patients securing results at the various hydrotherapeutic and osteopathic institutions.
The first part of our discussion is to be taken in the prophylactic treatment of this disease. Here we should begin by educating the children of the great family of rheumatism. Next, in case there is a history of previous articular rheumatism it behooves us to advise against exposure to cold for fear that this abarticular trouble may come on at any time. In immediate prophylaxis we have the treatment of all throat affections, sinus troubles, and pyorrhea alveolaris. This latter is of marked importance. Then, too, we must guard against rheumatic symptoms of certain intoxications, as iodism, plumbism, food poisoning, and autointoxications.
The second part of our discussion will be given over to the general measures to be used in a given case.
1. General directions: The first thing to impress on the patient is rest and this means rest to its fullest extent—that is in bed. If this idea is fully carried out the duration of the disease is much shortened. We need but mention here that the room should be light and airy. If we are dealing with a severe case a nurse should be in constant attendance.
2. The diet as a routine should be liberal and consist of milk, eggs, light meats, farinaceous articles and cruciferous vegetables. Between the regular meals buttermilk may be allowed ad libitum. The drinking of water is pushed to its fullest extent.
3. The next in order of general treatment is hydrotherapy. This phase of the subject is much neglected by the general practitioner and is the reason that our various hot springs have their repute. Very few in the general field of medicine use this measure to the fullest advantage. After a thorough general examination we should outline the course of baths to be given and the duration. If in a private home the general bath should be used daily, increasing the temperature of the bath as judged by the condition of the patient. The duration of the bath varies from five to twenty minutes, after which I give either a blanket or alcohol sweat. The length of time this is continued also varies with the condition of the patient. During this treatment all the hot liquids, that can be comfortably borne by the patient, are given.
Other measures that may be used are the various hot air equipments that are on the market. My personal observation has been that moist heat has much the preference.
4. The question of massage comes up at this point and has much to commend it, but always with the general rule, that it is not to be instituted until after the pain and tenderness have been under control for at least twenty-four hours. The massage should be general, with special attention to the area involved. One should always begin with light treatments. The success of the osteopath in the treatment of muscular rheumatism is due to the fact that he usually sees these patients after the acute symptoms have abated, but allow him to use his manipulations in an early case, and he is usually not called upon to give the second treatment.
5. In some cases of lumbago and other localized muscular troubles we do not have results with any of the general methods at hand. Here I have used acupuncture to good advantage. Of use also has been the injection of ten c. c. ice cold normal salt solution. The injection is made directly into the muscle involved.
6. Medicinal: The medicinal treatment I have purposely left to the last, for it is fully discussed in all works on treatment. In case of severe pain where our other methods are still to be instituted, we may have to use the opiates. Personally I use one or two injections of morphine in preference to the other derivatives of opium. Here, as in articular rheumatism, the salicylates stand out preeminent. My directions are to give large hourly doses until symptoms of intoxication appear, and then rely on smaller doses. Sodium bicarbonate is given to lessen the gastric irritability. In cases where the gastric symptoms are such as to preclude their use, the hypodermic injection of sodium salicylate or of salicylic acid in oil may be tried. Here also we may mention the use of sodium salicylate per rectum. Instructions are given to use fifteen grain suppositories four or five times daily, but always looking out for rectal irritability.
In chronic cases the iodides and arsenic may be of much benefit. As in other forms of rheumatism, we must combat the secondary anemia. A friable pill of iron carbonate, extract of nux vomica, and arsenic may be used three times daily after meals.
Constipation is to be combated with the salines or vegetable cathartics. This feature is of marked importance, for when the bowels do not act rheumatism is usually much worse.
For local use we have the twenty per cent. salicylic acid ointment or a liniment of oil of gaultheria. After these local applications we may apply the flannel jacket or bandages with the addition of local heat— with water bottles or electrical pads. The constant current used locally is of some benefit.
The third part of our discussion comprises specific medication. First to be considered is muscular rheumatism of a gonorrheal nature. Here
we must treat the local symptoms and institute a course of mixed vaccine. Much of the general treatment given above should be instituted. Internal medication is of no benefit. Next we have the muscular pains of syphilis. These are to be treated by mercury rubs or injections and possibly salvarsan. We must also mention the use of quinine in the complication of muscular rheumatism with malaria.

The general practitioner is now called upon to decide whether or not to use an alleged specific for all forms of rheumatism of a nongonorrheal character. I refer to the phylacogen treatment. As a personal measure I have never instituted the treatment, for I could not see my way clear in justice to my patients. However, I may add, that many cases have been brought to my attention in which this treatment has been employed without any benefit, and in several with much detriment to the general health of the patients.

(To be concluded.)

Therapeutic Notes.

Treatment of Seborrhea Sicca.—C. Sahatić, in Progrès médical for March 1, 1913, states that in the treatment of dry scaly seborrhea of the face mild measures should alone be employed, as unduly energetic methods may bring on eczema. Washing with hot water alone, without soap, is sometimes sufficient to overcome the condition; where this is not the case a teaspoonful of salt or sodium bicarbonate may be added to the wash water. If this fails the following solution should be applied locally every evening, with a pledget of cotton:

| R | Acidi salicylici, gr. xv (1 grammes); Alcoholis (65 per cent.), 5iiss (10 grammes); Aquae, 5iiss (100 grammes). |
| M. | ft. lotio. |

After using this preparation the skin should be dried and the following ointment applied:

| R | Zinci oxidi, 3i (4 grammes); Petrolatim, 5vi (25 grammes); Adipis lane hydrosti, 5iiss (10 grammes); Aquae rose, 5iiss (100 grammes). |
| M. | ft. unguentum. |

Where the condition persists in spite of these preparations more active treatment is justifiable. If the skin is dry ointments containing tar, oil of cade, or oil of birch may be used:

| R | Olei betule, mv (1 grammes); Rosorcinolis, gr. iv (0.25 grammes); Zinci oxidi, 3i (4 grammes); Adipis lane hydrosti, 5iiss (10 grammes); Petrolatim, 5vi (25 grammes). |
| M. | ft. unguentum. |

If the skin is red and the scales greasy and moist a weak potus-siam sulphide lotion—ten drops in a glassful of water—or one containing the folwing powder, may be used:

| R | Sulphuris praecipitati, gr. xv; Tali pulvis, 5iss; Misc. |

Trouble of this latter type constitutes a connecting link between seborrhea and eczema. The treatment customary in eczema may thus become indicated.

Treatment of Hyperchlorhydria.—Anthony Bassler, in the American Journal of Gastro-Enterology for January, 1913, in addition to describing the dietetic treatment of these cases, recommends that alkalies be given in one of the following forms:

1. Magnesii oxidi, gr. v (2 grammes); Bismuthi subcarbonatis, 5vi (20 grammes); Sodi bicarbonatis, 5iiss (10 grammes); Sodi carbonatis suspicati, 3i (9 grammes); Sacchari lactis, 5iiss (100 grammes); Fiat pulvis.
2. Magnesii oxidi, 5iiss (10 grammes); Bismuthi subcarbonatis, 5v (20 grammes); Syrupi acacie, 5iiss (10 grammes); G. s. Acue destillata, q. s. ad 5vii (200 grammes); Fiat mistura.

Sig.: One half teaspoonful in water, one, two, or three hours after meals.

If a powder or mixture is not desired, tablets may be prescribed:

1. Magnesii oxidi, 5iiss (5 grammes); Misture rhei et sodic, 5vii (200 grammes).
2. Sig.: One teaspoonful in water after meals.

M. Sig.: One tablespoonful in water after meals.

For a mechanical sedative effect on the gastric mucosa, the following combination of Stockton's should be used:

1. Cerii oxalatis, 5iiss (10 grammes); Bismuthi subcarbonatis, 5v (20 grammes); Magnesii carbonatis, 5x (40 grammes).
2. Sig.: One teaspoonful every four hours.

For a mechanical sedative effect on the gastric mucosa, the following combination of Stockton's should be used:

1. Cerii oxalatis, 5iiss (10 grammes); Bismuthi subcarbonatis, 5v (20 grammes); Magnesii carbonatis, 5x (40 grammes).
2. Sig.: Take one before meals.

For a mechanical sedative effect on the gastric mucosa, the following combination of Stockton's should be used:

THE ANTITUBERCULOSIS WORK IN THE
EAST RIVER HOMES CONDUCTED BY
THE ASSOCIATION FOR IMPROVING
THE CONDITION OF THE POOR.

Among the papers presented at the recent annual meeting of the National Association for the Study and Prevention of Tuberculosis in Washington was a notable report by Dr. Edward C. Brenner, describing the first year’s operations of the Home Hospital in New York city. This unique institution marks a new departure in methods of combating tuberculosis in that it constitutes the first really adequate attempt at home treatment and control of indigent cases of tuberculosis in this country.

Soon after the completion of the East River Homes, which were built with every modern hygienic device to bring sanatorium conditions as far as possible to the city patient, the Association for Improving the Condition of the Poor leased for a term of three years an entire section, consisting of twenty-four apartments. The objects of the association were not only to care for the tuberculous patient, but also for the family as a unit, to prevent the spread of the disease from the afflicted to the well, and particularly to protect the children from infection, to cure incipient patients, to preserve the family from sinking into dependency, and to restore at least to partial earning capacity the patients in moderately advanced cases. To carry out these objects a sufficient medical and nursing staff was provided, and, where necessary, the income of the family, crippled in its resources by the illness of its breadwinners, was supplemented sufficiently to relieve the patient of the anxiety which is so often an unfavorable factor in the treatment of the tuberculous poor.

During the past year there have been cared for a total of seventy-nine patients, including thirty-four children, distributed in twenty-seven families containing also fifty-six presumably healthy members, not a few of whom, however, were ill nourished, anemic, and likely candidates for tuberculosis in the unfavorable environment from which they were removed. The results obtained compare very favorably with those of sanatorium treatment, sixty-one per cent. having been apparently cured, twenty-two per cent. having had their disease arrested, and eleven per cent. being much improved. A striking feature in practically every case has been the marked gain in weight during the first two months of residence in the East River Homes. This in itself is an indictment of ordinary tenement housing conditions. The results have been especially good in the care of children, not only for those who are frankly tuberculous, but also for the undeveloped, marasmic, and puny infants which are so numerous in the squalid tenement homes.

The economic showings of this valuable experiment of the Association for Improving the Condition of the Poor promise to be as satisfactory as are the medical results. If it can be demonstrated that the tuberculous poor can be efficiently cared for at home with actually less expense than is entailed in breaking up the family, placing the patient in sanatorium or hospital and the children in charitable institutions, an important step toward the solution of a difficult question has been taken.

HOOKWORM DISEASE.

Humankind is prone to look to the macroscopic, while losing sight of the microscopic, for the causation of untoward epic events. Historians, for example, have almost entirely ignored the material, physical reasons for the deterioration of the Greek race, once the noblest in civilization and the fountainhead of most others since its Golden Age; in point of fact the decline and fall of Hellas began when Alexander and his men brought back anopheles and malaria (one of the most enervating of diseases) from terrible old Mother India. Here, as so oftentimes elsewhere in history, did the conquered land avenge itself on its conquerors, and the
EDITORIAL ARTICLES.

TROPICAL DISEASES IN THE UNITED STATES.

At first thought there does not appear to be any very intimate connection between the United States and tropical diseases, but, unfortunately, the association is much closer than generally imagined. Although this country is in the so-called temperate zone, we are approaching a season that in many of the States will indeed resemble the weather that is thought to be peculiar to the tropics. It therefore behooves the physicians of the country to be on their guard against the possibility of some alien disease gaining a foothold, or, if already present, from increasing. In past years there was not so much danger, because the communication between widely separated lands was slow and it took as long to go from city to city as it does now from one country to another. Consequently, tropical diseases, with some exceptions, did not demand much attention. But conditions now are very different; communication is rapid, and thousands of immigrants from all parts of the world are pouring in. Of course, the barring out of disease is the correct method, but that is not always successful; so all physicians should be prepared to recognize the invader whenever or wherever it appears.

When a list of such diseases present in the United States is made it assumes a distinctly formidable aspect. The eastern coast does not include so many, for it is in some respects further away from the tropics, but the epidemics of yellow fever that have occurred from New York as far down as the Gulf are historic. To-day in many parts of the country the stegomyia is present in large numbers, and all that is necessary is the importation of a case of fever. Along the southern portion of the Mississippi Valley many cases of abscess of the liver occur, and, according to the statements of numerous physicians in that part of the country, this condition is secondary to amebic dysentery. In Mexico, between whose territory and ours there is no sharp boundary line, typhus fever is endemic, and Brill's disease is also found. Inasmuch as the latter affection, when experimentally produced, gives immunity to typhus, there must be a very intimate relation between the causative factors of the two diseases. If we go to the Pacific Coast it will be found that bubonic plague must be carefully
guarded against, as one serious outbreak has occurred there and many rats and squirrels have been found infected; consequently, it is an ever present danger. To the diseases mentioned must be added leprosy, one which is supposed to be distinctly Oriental, if not necessarily tropical, but which does occur in northern countries. It is present, though the cases are not numerous, in all parts of the United States, from Louisiana to Wisconsin, from New York to California. Although none of the trypanosome infections of man have occurred primarily in this country, cases of these have been met within our confines, and as we have plenty of biting flies, some such might be capable of playing host.

It would, therefore, seem more necessary than ever that the possibility of such infections be kept in mind, and that every graduate in medicine be sufficiently well informed as to be aware of the dangers of such foreign invaders.

**INSANITY AMONG IMMIGRANTS.**

The article dealing with mentally defective immigrants, written by Senior Surgeon George W. Stoner, Chief Medical Officer at Ellis Island, and appearing in the *Journal* of May 20, throws new and heretofore unexpressed light on the immigration question in relation to the increased number of insane inmates of our public institutions. Especially is this interesting in view of the recent attempts at legislation aimed at the immigrant, on the plea that a large number of them are undesirable, because they are either actively or latently defective and thus tend to increase the burdens of the State in their support, or have a tendency to lower the eugenic standard of this country. If, however, as Stoner says, only about thirteen per cent. of the insane admitted to public institutions are aliens who have been here less than three years and whose mental condition can, therefore, be ascribed to a mental constitution defective before arrival, then the immigrant population is showing up remarkably well; when it is considered that the influences working upon a newly arrived immigrant are of such a character, probably because so different from the conditions under which he was living previously, as to predispose to a breakdown of some kind. In an immigrant the rapidity with which life here, and of a bewildering kind, moves about him, is apt to cause a mental vertigo which must sooner or later take him from his feet. But, in spite of this tendency, it does not seem to take the average immigrant very long to get into the whirl himself—much sooner in fact than natives of this country would, under similar circumstances—and be swallowed up and assimilated with the rest of the people. Indeed, Boas demonstrated that even their physical character changes in the succeeding generations.

To a large degree the reason why immigrants flock to our public institutions is because they have been hearing, on the other side, of our wonderful public institutions and the treatment received therein, and they do not hesitate, on the slightest provocation, to apply to them; whereas the native American naturally shuns them either from pride, fear of publicity, or other reasons not holding with the immigrant. Physicians practising in foreign settlements have this very complaint to make, that the people have more faith in institutional treatment than in private, even where they can afford the latter.

The increase in the insane population of public institutions is general all over the civilized world, and is not merely local here and due to immigration. It is the stress of modern civilization which is at the root of the increase of insanity; so much so that the public is now aroused to the necessity of combating it. The large increase in the number of suicides in recent times is another manifestation of the increasing tendency to mental breakdown. For, in spite of the fact that in law suicide is not necessarily an act of an irrational mind, medical men are inclined to place it at the door of a psychosis. The increase in insanity is, therefore, an evil of civilization and of the civilized, and not of those lacking it, as exemplified by the immigrant. It would be interesting, in view of the fact that a certain proportion of the insanity in the public institutions is almost wholly ascribed to immigrants and immigration, to investigate the causes of the insanity in the admittedly larger proportion of natives; then perhaps the immigrant would in large part be freed from the entire guilt, and beside, it would leave our minds open to finding possible causes in another direction. At any rate, ascribing the increase of insanity to the large immigration and leaving it there, is unscientific, to say the least. A little further information on this question would be edifying.

**INTRAMUSCULAR INJECTIONS OF MERCURY (EMULSION) IN THE TREATMENT OF SYPHILIS OF THE NERVOUS SYSTEM.**

L. L. Cazanavette, in the *New Orleans Medical and Surgical Journal* for May, states emphatically that mercury has been, and is still, our best weapon against the ravages of the spirochete, and of value in all stages of syphilis. While admitting that remarkable results have been obtained by a single dose of salvarsan, it is not only necessary to
repeat the injection of salvarsan two or three times at intervals of a few weeks, but to follow this by mercurial treatment, in order that the spirochete may be destroyed and the disease cured. The advent of salvarsan, according to the writer, has helped to strengthen the belief in the therapeutic possibilities of mercury. In the treatment of syphilis of the nervous system rapid mercurialization is necessary to arrest promptly the ravages of the disease. The writer's favorite method is the intramuscular injection method, as this has several advantages: The treatment is only in the hands of the physician, and the amount of mercury administered is small. Salivation is infrequent and the amount absorbed into the system is definite. Finally, there is no disturbance of the alimentary canal. He favors the use of the biniiodide in oily solution.

**News Items.**

**Changes of Address.—**Dr. R. Pettit, to 544 West 15th Street, New York.

**Philadelphia Laryngological Society.**—At the annual business meeting of this society, held on June 17th, the following officers were elected: President, Dr. E. B. Gleason; vice-president, Dr. George W. Mackenzie; secretary and treasurer, Dr. Charles A. O'Reilly. For two vacancies in the executive committee Dr. Ross Hall Sellem was elected to serve for two years, and Dr. Fielding O. Lewis for one year.

**American Society for Physicians' Study Travel.**—At a meeting of this society, held in Minneapolis on Monday, June 16th, the following officers were elected to serve for the ensuing year: Dr. J. A. D. Pinkie, president; Dr. William J. Mayo, of Rochester; Minn., first vice-president; Dr. Llewellys F. Barker, of Baltimore, second vice-president; Dr. Frank Billings, of Chicago, third vice-president; Dr. Albert Bernheim, of Philadelphia, general secretary.

**Resolution Adopted by American Association for Cancer Research.**—At the annual meeting of the American Association for Cancer Research, held on May 5, 1913, the following resolution (the report of the Committee on Education and Public Education) was unanimously adopted:

1. It is the sentiment of this association that:
   a. The present instruction of medical students in the symptoms and treatment of cancer is seriously deficient.
   b. The medical curriculum should include special lectures in the clinical departments dealing specifically with this subject.
   c. The universities should provide competent lecturers in this subject to address the local medical societies.
   d. The associate members of the association should be urged to take up the question of the proper methods of approaching the public on the subject of cancer.
   e. The activities of this association should at present be chiefly confined to the education of the medical profession.

2. This resolution shall be sent to the deans of the medical schools and the secretaries of the State medical societies in the United States and published in the medical press.

**A Hindi Translation of Doctor Knopf's Prize Essay on Tuberculosis.**—Dr. Balkrishna Sharma, of Delhi, India, has sent to this country a number of copies of a recent Hindi translation of Dr. S. Adolphus Knopf's international prize essay on tuberculosis. Doctor Balkrishna has been fortunate enough to find a philantrophic publisher so that the essay can be retailed at five annas (about ten cents). In view of the great prevalence of tuberculosis in India and the fact that the Hindi language is spoken by more than eighty million people, the desire to educate the masses in the combat of tuberculosis in that part of the world is a gratifying sign of the universal progress of the antituberculosis campaign. A new issue of Doctor Knopf's Seventh American Edition of "Tuberculosis at Distant Centers and How to Combat It" has just come out so that, since the appearance of the original first German edition in 1900, there have appeared in all, including this Hindi and the recently issued French, German, Russian, Italian, Chinese, Swedish, Danish, Spanish, and sixty different editions in various languages spoken in Europe, America, and Asia.

The J. Hood Wright Hospital Changes Its Name.—The J. Hood Wright Memorial Hospital, which was incorporated in 1868 as the Manhattan Dispensary, has got permission from Supreme Court Justice Page to change its name to the Knickerbocker Hospital. The petition said that since Mr. Wright died the years service of the district served by the hospital has increased greatly and the necessity for more funds has increased proportionately. The hospital managers and Mr. Wright's heirs believe that the present name of the hospital leads to the belief that it is so little endowed as to require outside assistance, and for this reason none has been forthcoming. It is said that Mr. Wright desired outsiders to contribute toward the maintenance of the institution.

**Examination for Assistant Surgeons in the Public Health Service.**—Boards of commissioned medical officers will be convened to meet at the Bureau of the United States Public Health Service, Washington, D. C., and at the Marine Hospitals in Boston, Chicago, New Orleans, and San Francisco, on Monday, July 7, 1913, and Monday, August 4, 1913, at 10 o'clock a.m., for the purpose of examining candidates for admission to the grade of assistant surgeon in the Public Health Service, when applications for examination are received at the Bureau. Candidates must be between twenty-three and thirty-two years of age, graduates of a reputable medical college, and must furnish testimonials from two respectable persons as to their character. For further information, or for invitation to appear before the board of examiners, address Surgeon General, United States Public Health Service, Washing- ton, D. C.

**Changes in the Staff of the Rockefeller Institute for Medical Research.**—The board of directors of this institute announce a number of changes in the staff for the coming year, among them being the following new appointments: Wade Hampton Brown, M. D., associate in pathology and bacteriology; Charles T.atar, assistant in pathology and bacteriology; Frederick Lamont Gates, M. D., fellow in physiology and pharmacology. The following assistants have been made associates: Frederick Burr La Flage, Ph. D., chemistry; James Bum- gardner Murphy, M. D., pathology and bacteriology; Ernest Meyer, Sc. D., chemistry, and Martha Wallstein, M. D., pathology and bacteriology. Michael Heidelberger, Ph. D., has been promoted, from fellow to assistant in chemistry.

Dr. G. Canby Robinson, formerly associate in medicine, has been appointed associate professor of medicine in Washington University, St. Louis. Dr. Jacques J. Bronfenbrenner, formerly assistant in pathology and bacteriology, has been appointed director of the pathological laboratory of the Western State Hospital, Pittsburgh. Dr. Richard Vanderhorst Lamar, formerly associate in pathology and bacteriology, has been appointed professor of pathology in the University of Georgia.

**Personal.—**Dr. Joseph A. Blake has resigned as professor of surgery in the College of Physicians and Surgeons, Medical Department of Columbia University, a position he has held for twenty-five years, and as surgeon to the Presbyterian Hospital, after five years' service in that capacity. Both resignations took effect on July 1st. Doctor Blake is retiring from these positions in order to maintain his private practice.

Dr. Francis Barnes, clinical director of the Government Hospital for the Insane, Washington, D. C., and Dr. Nicholas J. Dynan, senior assistant, have resigned their positions. An examination was held on July 2d to fill the vacancies.

Dr. Francis H. Donoghue, of Boston, has been appointed by Governor Foss to represent the State of Massachusetts at the Third International Cancer Congress, to be held in Brussels, Belgium, during the first week in August, and also at the Seventeenth International Medical Congress, which will be held in London, from August 6th to 19th.

Dr. Stephen J. Malier, of New Haven, Conn., has been elected chairman of the Connecticut State Tuberculosis Commission.

The degree of doctor ophthalmology was conferred upon Dr. George F. Libby, Dr. William H. Crisp, and Dr. Daniel J. Monaghan, all of Denver, by the University of Colorado, at the annual commencement held on June 4th. This degree was never before conferred by an American university.
The American Medical Association,
Sixty-fourth Annual Meeting,
MINNEAPOLIS, JUNE 16 TO JUNE 20, 1913.
(Concluded.)

Report of Sections.
SECTION IN SURGERY.
TUESDAY, JUNE 17TH.

Chairman's Address: The Surgeon and the Research Laboratory.—Dr. A. F. Jonas, of Omaha, urges closer cooperation between the operating surgeon and the experimental research laboratory. Modern surgery is a science more than an art, and must be based upon scientific laws, which alone can be obtained by laboratory experimentation. Clinical and bedside findings and observations are more important than those obtained in the laboratory, but are insufficient. Apparatus and thoroughly equipped laboratories are necessary to the carrying on of such work, but it should always be remembered that architecture and apparatus are secondary elements. The work of the laboratory must not be detached, as shown by the fact that the blood pressure apparatus had been used in experimental laboratories for fifty years before taken up by the clinicians.

Posterior Gastroenterostomy in Acute Perforating Ulcer of the Duodenum.—Dr. John B. Deaver, of Philadelphia, describes the symptomatology, as based upon a personal experience of over thirty cases. The condition is absolutely surgical, for death is certain without operation, and cure practically certain when the interference is instituted early. The diagnosis is commonly confounded with that of acute indigestion. The pain is sudden, violent, and agonizing; rigidity extreme. The symptoms all come on very rapidly, and are sufficient to make the diagnosis a surgical diagnosis. Time should not be lost in the making of blood examination, etc.; when in doubt, operate. Of twenty-six cases, particularly within twenty-four hours of the perforation, there were twenty-five recoveries and one death. The early peritonitis, that is up to twelve hours, is largely chemical, rather than bacterial, peritonitis, due to the escape of irritating secretions from the duodenum, which prepare the way for the subsequent bacterial invasion and usual result in fatal peritonitis. This is borne out by clinical and bacterial observations. He advises (1) infolding of the ulcer with plication of the duodenum to throw it out of function; (2) posterior no loop gastrojejunostomy; (3) pelvic tube drainage through suprapubic stab; (4) avoidance of irrigation; (5) appropriate aftertreatment, consisting chiefly of sitting posture, continuous enterocolysis, nothing by mouth until peristalsis is resumed, and ice bags applied to the abdomen. The results obtained make primary gastroenterostomy the operation of choice.

In the discussion Dr. William J. Mayo, Doctor Ochsner, and Doctor Coffee advised that in localities where a skilled surgeon could not be promptly secured the practitioner should close the perforation and provide adequate drainage; never perforating the gastroenterostomy, which should be reserved for the expert surgeon. An operation performed within the first twelve hours by the amateur would save many patients who if operated upon later by the most skilled surgeon in the world could not be saved.

Postoperative Ileus.—Dr. Angus McLean, of Detroit, presents the records of much experimental work on dogs, from which he made the following conclusions: Patients attacked by ileus die from the loss of body fluids, and not from toxemia. Hence, the proper treatment is that of supplying the body with fluids by enterocolysis and intravenous infusions.

Proctocolysis: An Experimental and Clinical Study.—Dr. Hugh H. T. Kent, of Roanoke, Va., has made a study of the comparative value of plain tap water as a normal saline solution in about 2,500 cases. His conclusions are: Normal saline showed no advantages over the plain tap water, but had the following disadvantages: There was danger of much re-estimation, and increased amount of thirst, some of the individuals actually tasting salt; and some of the patients showed both edema and albuminuria.

Etiology and Significance of Membranes about the Cecum and Colon.—Dr. David Cheever, of Boston, gives the results obtained from a study of embryos and infants. The conclusions reached are that there are probably several varieties due to several etiological factors, some congenital, that is embryonic, and others inflammatory. He cites evidence in an endeavor to prove that they are rarely of clinical significance.

Anaphylaxis in the Diagnosis of Cancer.—Dr. J. Louis Rankoff, of Cincinnati, describes a method of injecting sensitized guineapigs with human blood serum for the purpose of diagnosticing cancer. In a careful study of fifty or more cases he found that ninety-two per cent. of advanced, incontestable cases of carcinoma gave positive reaction, while eight per cent., were negative. The blood serum of tuberculous and luetic patients was also tested and found not to give the reaction. He hopes that the test ultimately may prove of value as an aid in the early diagnosis of concealed abdominal carcinoma.

WEDNESDAY, JUNE 18TH.

External Bone Clamp versus the Internal Bone Plate in Fractures of Long Bones.—Dr. Leonard Free man, of Denver, mentions the following advantages: The simplicity of its use with minimum disturbance of the tissues; ease of removal at any time, which may be accomplished without anesthesia; fewer cases of delay or nonunion; and the great advantage of not burying a permanent foreign body in the tissues. He asserts that the reduction is just as perfect as with the internal bone plate. The clamp should be preferred not to be put too near the epiphysis in compound fractures, particularly when infection is anticipated. The clamp is by all means the method of choice, not alone not doing harm, but the saving them in cases of compound fracture.

In the discussion Dr. J. B. Murphy recommended the use of the external bone clamp, saying that the plate should never be used in cases of compound fracture.

Doctor McArthur reported very satisfactory employment in 216 cases of open fracture of the worst character occurring during the building of the Panama Canal.

The Mechanism of the Production of Fractures.—Dr. Emmett Rixford, of San Francisco, presents the subject from the standpoint of the teacher, great stress being laid upon the fact that the principles of the mechanism are most important to the proper understanding on the part of the student. Incomplete fractures in children in the majority of cases are fractures by buckling; they are improperly designated in this country "green stick" fractures. The Germans more correctly call them subperiosteal fractures. Fractures of adult long bones usually result from tensile stress. Spiral fractures result from twist, and so occur always in the direction of the twist. Fractures of short bones result from compressive or tensile stress.

Surgical Management of Injuries to the Elbow Joint, Primary and Secondary.—Dr. John B. Murphy, of Chicago, states that the proper treatment of joint injuries is bringing more discredit to the profession than any other branch of the practice. The time is not distant when the profession will be held financially responsible for these avoidable evils. Poor results in the treatment of injuries of the elbow joint follow luxation, and fractures are next in frequency to
those in Colles's and Pott's fractures. By more careful and thorough diagnosis, an insistence upon perfect reduction, and the maintenance of the same, these results can be avoided. When perfect reduction can be obtained and maintained by conservative bloodless manipulation, over the spot and the raising of fragments for an attempt to. Fractures of the external and internal condyle, or both, may be nailed with the ordinary eight, ten, or twelve pennyweight carpenter nail, through a small nick in the skin. This can be done with impunity, and great mastery and the nailing of fragments for an attempt to

variously the proper site for amputation. Even with the main trunks completely blocked, the collars will be sufficient to nourish the flaps in this location.

Extrathoracic and Intrathoracic Esophagoplasty.—Dr. Willy Meyer, of New York, urges complete radical excision of the diseased portion of the esophagus and the diseased parts widely and providing for the replacement of the function of the esophagus later. A tube outside the thorax will enable the patient to swallow as well as inside, or plastic formations of new tubes by employment of the closed small intestine, which has been successfully employed. The rubber tube connection employed outside the thorax, between the stomach opening and the oral opening, is very satisfactory. Cancer of the lower third of the esophagus, in the light of recent animal experiments, will probably before long be likewise radically dealt with.

Oration on Surgery: Who Shall Do Surgery?—Dr. William D. Haggard, of Nashville, believes that modern surgery has made such great advances and become such a large subject that special preparation is required for its practice. The profession must insist upon better trained men; otherwise great discredit will result. Of 4,500 graduates there are 3,000 hospital interns, which is not合格。if the 3,000 interns do not graduate, the profession will require a fifth hospital year. He urges the establishment of special courses for the training of surgeons, and then the conferring of a special degree, as of M.S.—Master of Surgery—to those qualifying themselves.

Symposium on Infections.

Chronic Focal Infections and the Causative Factor in Chronic Arthritis.—Dr. Frank Sillinger, of Chicago, states that as a result of work, experimental and clinical, performed in close cooperation by medical, dental, and veterinary practitioners, a great deal of information regarding chronic arthritis, myositis, and neurosis has now been collected. The conditions of chronic arthritis, myositis, and neurosis have now been collected. The conditions are that these are practically all due to chronic focal infections. Focal infections of the tonsils, of the sinuses of the head, of the dental alveoli, of the prostate, of the seminal vesicles, and of the urethra; and of the scalp, of the skin, of the gums, and of the nails, are causative. The treatment is removal of the cause. Gratifying results have been obtained by autogenous vaccines.

Infections of the Prostate and Seminal Vesicles; The Role in Toxemia.—Dr. Hugh H. Young, of Baltimore, says that prostatitis and vesiculitis are very commonly involved in gonorrheal urethritis without symptoms manifesting themselves in later life by rheumatic infections. Prostatitis is frequently caused by infections from the rectum, and it is commonly in cases of hematuria. These lesions frequently cause lumbago, sciatica, multiple arthritis, bursitis, myositis, and nervous symptoms, all of which have been cured by attention to the cause. For prostatitis and vesiculitis the treatment is massage, prostatectomy, or incision of the seminal vesicles.

Injection of Boiling Water for Hyperthyroidism.—Dr. Miles F. Porter, of Fort Wayne, Ind., from a clinical observation of over twenty cases, recommends the employment of boiling water for cases of mild cases of hyperthyroidism. The immediate effect of the injection of the boiling water is the actual destruction of the thyroid tissue in the vicinity of the injection; resulting in diminution in the quantity of tissue forming the secretion.

THURSDAY, JUNE 10TH.

Nephritis as a Surgical Problem, and Its Treatment as a Preliminary to Operation.—Dr. J. F. Percy, of Chicago, Ill., subjected the use of desoxycorticosterone in the gland in large doses as a means of improving the surgical risk in cases of nephritis. He reports some cases of actual cure of the condition. The treatment is contraindicated in cases complicated by incompensation of the heart, in the chronic nephritis, in any cases of liver disease, or in the kidney secondary to infections of the genitourinary tract. The thyroid extract may be of value as an agent in cases of suppression of the urine.
Technic of Roentgenography of the Gastrointestinal Tract, and Interpretation of Screen and Plate Findings.—R. D. C. Sherman, of Rochester, Minn., from the observance of a large number of more routine x-ray examination, many unsuspected lesions being found by so doing.

The Added Responsibility of the Surgeon when Called on to Treat Surgical Lesions in their Earliest Stages.—Dr. J. C. Bloodgood, of Baltimore, makes a plea for greater attention to and more careful examination of patients with mild symptoms. A failure to diagnostically recognize malignancy in its incipient stage is a much greater mistake than the failure to recognize it in the more advanced stages. The condition is curable by operation, and in the later never. The real problem of surgery to-day is the one of making early diagnoses, and particularly in cases of malignancy.

Petals Perforating Pools and Their Relation to Post-natal Acute and Chronic Occlusions of the Large and Small Intestine.—Dr. J. Rilus Eastman, of Indianapolis, cites cases of acute obstruction of the colon due to Jonnese's parietocolic fold, or Jackson's membrane. Large fragments without any cause at various planes in the alimentary canal by these membranes. Many of the cases of intestinal stasis and chronic auto-intoxication are caused by the persistence of these fetal membranes and folds.

Symptoms and Diagnosis of Membranous Pericoclitis.—Dr. Jarez N. Jackson, of Kansas City, Mo., states that pain along the course of the ascending colon, general diffuse tenderness over the whole abdomen, constipation, mucous diarrhea, digestive or alimentary congestion and anemia, all resulting in loss of weight, are the main symptoms in the diagnosis of membranous pericoclitis. Roentgenography is of great value in demonstrating the stasis and sites of obstruction. Increased temperature and pulse disturbances are always absent.

The Necessity of Preserving the Periosteum in Bone Transplantations.—Dr. Clarence A. McWilliams, of New York, in this paper, which is based upon a large amount of experimental work in bone transplantation, concludes that the life of the bone graft depends exclusively upon its blood supply, the periosteum or marrow present or absent having no particular effect. Small fragments of bone demuced of their periosteum will live in tissues without absorption, due to a rich blood supply. Larger fragments are always absent in cleft bone supply. The periosteum is bone forming and lives when the bone dies, because of its ability to appropriate nutrition. Complete subperiosteal bone resection is followed by the reforming of the periosteum.

Roentgenographic Examination of the Liver and Biliary Passages.—Dr. James T. Case, of Battle Creek, Mich., has found the x-ray examination of the liver to be of value in diagnostic changes in the size and shape of the liver, local tumors, hepatic and subphrenic abscesses, adhesions, and malformation in many cases giving valuable information in cleft blood supply. The periosteum is bone forming and lives when the bone dies, because of its ability to appropriate nutrition. Complete subperiosteal bone resection is followed by the reforming of the periosteum.

Original Uses of the Bone Graft in Surgery.—Dr. Fred H. Abee, of New York, reports the results of the use of bone graft in the treatment of fractures of the spine, all long bones, neck of the femur, and club foot; showing that the number of cases and of pictures as proof. His results are very satisfactory. Doctor Abee uses graft with periosteum and bone marrow, believing the latter two, though not always essential, to be of value in insuring future life of the graft.

Symposium on Anesthesia.

Nitrous Oxide and Oxygen Anesthesia.—Dr. Harry G. Sloan, of Cleveland, believes that nitrous oxide and oxygen anesthesia particularly given in very bad surgical risks; these taking it the easiest. It is the anesthesia de luxe; it is pleasant to take and causes less subsequent nausea. Diabetics do well with this anesthetic. Owing to their severe lesions, complete elimination of pain and of pictures as proof. His results are very satisfactory. Doctor Abee uses graft with periosteum and bone marrow, believing the latter two, though not always essential, to be of value in insuring future life of the graft.

Intratracheal Insufflation Anesthesia (Meltzer-Auer).—Dr. Charles H. Peck, of New York, gives his personal experiences with 334 patients operated upon at Roosevelt Hospital during the past two years under this form of anesthesia. The cases were distributed as follows: Operations on the thorax, sixteen; head and neck, fifty-six; goitre (simple and exophthalmic), sixteen; the kidney and ureter, twenty-two; breast, twenty; abdomen, 116; miscellaneous operations, eighty-eight. The advantages and disadvantages of this form of operation are explained.

Local Anesthesia.—Dr. J. F. Mitchell, of Washington, D. C., refers to the extensive use of local anesthesia in Europe, and predicts its greater employment by American surgeons. It is impossible to do real accurate work in the aged, and whenever general anesthesia is contraindicated. By the intravenous method of Bier all major surgery of the extremities may be performed, the particular value of its employment being the protection of the central chiastm from shock due to the blocked condition of the nerves. Practically all surface surgery of the torso, and all of the major surgery of the extremities may be performed under local anesthesia. Novocaine is the most anesthetic of all.

Surgical Aspects of Intestinal Stasis from an Anatomical Point of View.—Dr. John E. Summers, of Omaha, points out that mechanical obstruction and interference are responsible for a large number of the cases of intestinal stasis. Neglect of the function and disease of the nervous system also play a part and frequently result secondarily from the mechanical condition, forming a vicious circle. The recent interest in these various conditions has been occasioned by the writings of Lane and Jackson, and others, who, however, only redescending conditions observed and recorded by Jonnese, Juvara, Treves, Reid, and others. These are mostly due to embryonic conditions. Some are of inflammatory origin, and give interesting histories, which possibly are the basis which can be relieved alone by operative interference.

Friday, June 20th.

Gastric Tetany.—Dr. W. L. Rodman, of Philadelphia, has met with great satisfaction in the treatment of gastric tetany by means of gastroenterostomy or pyloroplasty. The relief obtained with the operation is so rapid that the evacuation in the treatment is that of gastric drainage. Gastric lavage continued for long periods of time may carry a patient along, and now and then result in a cure. Sedatives such as morphine, bromides, and chloral are indicated.

An Experimental Study of the Mobilization of Ankylosed Joints.—Dr. Nathan Allison and Dr. Barney Brooks, of St. Louis, present conclusions reached as a result of a review of the literature and personally conducted experiments and clinical work. Mobilization of ankylosed joints is based upon the freeing of such ankylosis, and the interposing of materials to prevent a return of the ankylosis: Cartilage membrane, Bierr membrane, silver nitrate fascia, fascia with nitrate, free cartilage and killed fascia. Among these the interposing of fascia has yielded the most satisfactory results.

Therapeutic Possibilities of Transfusion.—Dr. Bertram M. Berveheim, of Baltimore, states that transfusion of blood is indicated only in cases of exsanguination, but also in toxemias, and in many of the abnormal blood conditions, as splenic and pernicious anemias. It should be performed in earlier stages of these conditions to ascertain its real value, as the method gives promise of great value. The difficulty in the past has been that it has been performed usually only upon moribund patients, though even then with marked success at times. With a simplification of technic, its field of usefulness is being gradually widened and it is possible that the results of transfusion, Therapeutically, the field is still practically unexplored, although a beginning has been made.

Theory and Practice of Transfusion.—Dr. J. J. Hogan, of New Orleans, believes that transfusion of blood is indicated only in cases of exsanguination, but also in toxemias, and in many of the abnormal blood conditions, as splenic and pernicious anemias. It should be performed in earlier stages of these conditions to ascertain its real value, as the method gives promise of great value. The difficulty in the past has been that it has been performed usually only upon moribund patients, though even then with marked success at times. With a simplification of technic, its field of usefulness is being gradually widened and it is possible that the results of transfusion, Therapeutically, the field is still practically unexplored, although a beginning has been made.

Thyroglocial Cyst and Fistulas: Report of Three Cases.—Dr. Herman H. Gessner, of New Orleans, says that thyroglossal cysts and fistulae are of embryonic origin being remnants of tissue from the foramen cecum to the isthmus of the thyroid. The fistula always open in the median line of the neck, in contradistinction to those resulting from permanency of branchial cleft structures. The skagrams of injected fistulae are of great diagnostic and operative value. The treatment is by excision.
SECTION IN DISEASES OF CHILDREN.

TUESDAY, JUNE 17TH.

Chairman's Address: Radiographic Studies of the Intestines in Infants.—Dr. Henry D. Chapman, of New York, refers first to the difference in the results of studies after death and an x ray examination of the same parts during life. The great advantage of the latter method is that it deals with a living, functioning body. He then goes on to say that post mortem studies of the viscera have been largely neglected. He emphasizes the value of radiographic studies of movements of the viscera and the necessity of confirmatory conclusions from the movements observed. Two normal infants were given suspensions of bismuth by the mouth, and the contrast obtained by free passage through the bowel with x ray and the bismuth was found to pass from the sigmoid into the rectum in seven hours. Another series of experiments was made to determine the location of the sigmoid, the distensibility of the colon, the form and position of the hepatic and splenic flexures, and the patency of the ileocecal valve. Enemas of barium sulphate were given, and, after being forced beyond the sigmoid, the fluid quickly passed to the ecum. Marked variation in the size and position of the sigmoid was observed. From the evidence obtained in these studies it seems improbable that rectal tubes pass above the sigmoid.

The Use of the Roentgen Ray in the Diagnosis of Obscure Abdominal Conditions in Infancy and Childhood.—Dr. J. L. Morse, of Boston, states that by this method the diagnosis of cases which can be obtained in no other way. He presents illustrative histories, with many fine radiographs; the cases including pyloric stenosis, pyloric spasm, chronic gastric indigestion, splanchoplegia, abscessed intestines, and intussusception. The x ray is of value in determining the location of abdominal masses, whether these are ventral or dorsal, and a great help in the differential diagnosis between ileocolitis and intussusception. A cup shaped upper end of the shadow, after the bismuth meal has been given, is diagnostic of intussusception.

The Use of the Roentgen Ray in Pyloric Obstraction.—Dr. L.R. DeBuys, of New Orleans, makes a plea for early x ray studies of suspected cases of pyloric stenosis or spasm, and for further studies of such patients during childhood and even adult life. He cites cases of spasm with palpable pyloric tumor, and shows the difficulty of differentiation between spasm and stenosis. In stenosis, however, the delay in emptying the stomach after a bismuth meal is marked, and in spasm it is occasional. The speaker presents x ray plates showing various types of pyloric obstruction, and concludes with a demonstration of moving pictures showing peristaltic waves in a living infant.

Rupture of Mediastinal Lymph Node into Bronchus.—Dr. A.L. Goodman, of New York, reports a case in which there was a sudden development of dyspnea and cyanosis in a child. Tracheotomy was performed, and caseous material was discharged through the tube, affording relief of the symptoms. The following day an x ray examination showed enlargement of a mediastinal gland, and the conclusion was reached that the gland had ruptured during the introduction of the tracheotomy tube. Inoculation of guineapigs with the caseous material failed to cause tuberculosis, and in the symptoms of pressure from mediastinal tumor are (1) respiratory—dyspnea; (2) circulatory—cyanosis; (3) digestive—vomiting and associated meniscing. The condition is likely to remain undiagnosed unless an x ray examination is made. Radiographs of the case reported were shown.

WEDNESDAY, JUNE 18TH.

Report of Case of Staphylococcus Meningitis in a Child.—Dr. F. S. S. Churchull, of Chicago, reports this case, which, after thirty days' duration, was treated with sulfanilamide. There was marked relief of the symptoms within twenty-four hours, and the patient made a complete recovery.

Acute Acid Intoxication in Children.—Dr. T. C. Meyerc, of Berkeley, Cal., has found acid intoxication most frequent between the ages of two and ten years; the etiological factors being acetic and diacetic acid. The primary cause is still obscure, but he believes that the condition may be due to any chronic infection, such as an intoxication producing interference with the storing of glycogen in the liver. The treatment consists in removal of the above mentioned factors, especially by means of a diet poor in fats and rich in fruits and cereals, and by the administration of glucose and sodium bicarbonate by mouth and rectum.

Dr. J. Z. Hohrsky says he thinks there is little value in the removal of adenoids in this condition. He has frequently found that the local symptoms cleared up during the attack, and he considers the affection related to migraine.

Dr. I. A. Ant has seen the acidosis sometimes develop at the time of weaning, causing vomiting and diarrhea at first, and, later, rapid breathing, pallor, and obstinate constipation. The treatment consists in giving the patient acetone and diacetic acid. He reports three cases occurring in one family, and states that the third child was saved by treatment with glucose and sodium bicarbonate. The cause of the condition, he thinks, may possibly be a toxic protein.

The paper was discussed also by Doctors Snyder, Johnson, Morse, Price, DeBuys, and Lounbury.

The Protein Poison and Its Relation to Disease.—Dr. E. C. Verrall, of Chicago, and Dr. H. S. M. Morgan, which, has shown that all proteins, particulate and formless, cellular and in solution, contain a poisonous group. If any reason proteins taken into the alimentary canal escape digestion and are absorbed unchanged they undergo parenteral digestion, and it is this process that causes the protein to be found in the blood and tissues and manifests its full effect. In enteral digestion the poison is most marked in its action at or about the pepton stage. When the digestion is normal and proceeds beyond this point the protein is detoxified by further cleavage. The intestines of children are more permeable to proteins than those of adults, and this is the reason why infants suffer more largely than adults from gastrointestinal disturbances. There is no specific bacterium which can utilize the poisonous protein from infancy. Saprophytic bacteria may render the proteins of milk, and possibly of other foods, more readily absorbable. The symptoms of poisoning are: 1. Peripheral irritation; scratching (erythema; urticaria). 2. Incoordinative movements; air hunger. 3. Cliston convulsions of increasing frequency; death. He believes death is due to the pouring of lethal amounts of the protein poison into the circulation. The different bacteria cause liberation of protein in different tissues, giving rise to the symptoms of various diseases. Some forms of the protein tend to neutralize the protein poison, and this effect may explain the value of alkalies in acidosis.

The Nature of Ileocolitis from an Etiological Standpoint.—Dr. F. G. Good, of Chicago, presents the following theories regarding the cause of ileocolitis: 1. Direct bacteriological action, most commonly by the dysentery bacillus or the streptococcus. 2. Bacterial action on food, forming endotoxins. 3. Primary disturbance of metabolism. 4. Heat; he discusses the relations of each of these to the others, and expresses the opinion that the most important element in the etiology is the decomposition of food by the intestinal bacteria. In the discussion Dr. R. M. Smith said he believed that many cases were caused by direct bacterial action. In cases due to dysentery bacillus infection the patient did well when food with a high sugar content was given, but the reverse of this was true in some other forms of bacterial infection.

Nutritional Injuries Produced by Starch.—Dr. I. A. Ant, of Chicago, describes the chemical changes observed in the infantile organism from excessive starch feeding and the disastrous clinical results, and presents case reports.

Status Thymolymphaticus: with Report of Four Cases in One Family.—This paper is presented by Dr. W. L. Biering, Dr. D. L. Gompet, and Dr. J. A. Goodrich, of Des Moines. The four children all died suddenly between three and six months of age, with no known predisposing cause. In all the cases the autopsy showed enlargement of the thymus, spleen, and lymphatic nodes. X ray treatment was of most service in lessening the size of the lymphatic tissues, but, this treatment was not successful.

The Treatment of the Hemorrhagic Diseases of Children.—Dr. T. B. Cooley, of Detroit, states that in most
instances of these affections the blood is slow to coagu-
late; a condition due to a deficiency in fibrinogen or in 
prothrombin. A deficiency in calcium has never been 
found. The injection of horse or human serum is the

most valuable of all means of treating children with 
the latter there is less danger of anaphylaxis. He advises early

report to transfusion, and describes his own method of as-
piring blood from the donor and its immediate intrave-

nous injection in the patient. Treatment of Ingual Hernia in

Children.—Dr. A. E. Hertzler, of Kansas City, believes that truss treatment

is not only never curative, but may be extremely harmful. Operative treatment is the only escape, and it is certain

that for eleft palate and sarcoma of the jaw.

General Anesthesia in the Surgery of Children.—Dr. W.

C. Woolsey, of Brooklyn, assigns the following rea-
sons for the greater danger of anesthetics in children:

(1) Proportional greater heat radiation; (2) unstable

vasomotor system; (3) small air passages, liable to irri-
tation and occlusion; (4) status lumbicus. He believes ether

is the anesthetic of choice in children. Tracheal in-

sufflation is especially valuable for operations such as

those for eleft palate and sarcoma of the jaw.

Spasmodilia; with Special Reference to Familial

Reactions and "Repeated Absences."—Dr. J. P. Sedge-

wick, of Minneapolis, points out the probable relation of this

condition to disturbed calcium metabolism, and its

relation to other diseases (gout, scurvy) characterized by

convulsive attacks in which the "repeated absences" resembled petit mal, but were due to spasmom-

philia. Charts were presented showing electrical overex-

citability in different generations of several families.

Election of Officers.—The following officers were

elected for the ensuing year: Chairman, Dr. F. S.

Churchill, of Chicago; vice-chairman, Dr. L. R. De Buys,

of New Orleans; secretary, Dr. G. P. Gengebach, of

Denver; delegate, Dr. J. P. Sedgwick, of Minneapolis.

Report of the Children's Joint Committee of the Boston

College of Physicians and Surgeons, Dr. Richard M. Burnham,

of Boston, believes the complement fixation test valuable in

the diagnosis of questionable cases of gonorrhoea. He

reports a series of thirty cases of vulvovaginitis, seventy-

five per cent. of which were known to have been

prevented by proper home care; showing the importance

of the education of parents regarding the gravity of infec-
tion and methods of preventing it. The treatment, he

says, must be thorough and prolonged.

Roseola Infantum.—Dr. John Zahorsky, of St. Louis,

reports thirty cases in children under two years with the following clinical syndrome: Prodromal fever, with tem-

perature of from 103° to 105° F., of from three to five
days' duration. The temperature falls by crisis when the

eruption appears. Eruption is macular; most marked on the

trunk. No Koplik spots, and no catarrhal symptoms.

This affection differs from rubella in that the eruption
does not take on a crescentic form, and the disease is not

contagious. Practically all the cases observed were in

bottle fed infants.

Forms of Meningitis (Posterior Basic

Meningitis; Atactic Meningitis).—Dr. A. Sophian,

of Kansas City, states that turbid, sterile spinal fluid may be

found: 1. After a previous puncture; 2. after admin-

istration of Flexner's serum; 3. frequently in otitis media;

less frequently in meningococcus meningitis. There are

many forms of meningococci, some of which are not affected by

Flexner's serum. Posterior basic meningitis may give a

fluid containing meningococci, or may be sterile. The

cases usually show signs of pronounced intracranial pres-

ture, but local signs are not prominent, and few cutaneous

symptoms of fluid are obtained. He advises puncture of both lat-

eral ventricles and injection of serum if meningococci

are present in the fluid. The prognosis is very grave.

Leucocyte Counts in Epidemic Meningitis and Pneu-

monia.—Dr. J. H. Hess, of Chicago, instead using the

usual percentage method of differential counting, counts the

actual number of different cells. He considers leucocytosis in its relation to infection gener-

ally gives the result of leucocyte counts in epidemic meningitis,

before, during, and after treatment by serum. From

these may be derived indications for further treatment.

He describes the findings in the stage of anaphylaxis, and

the significance of the post-anaphylactic period, which measures the cost

of pneumonias of different types, as an aid to their classifica-

tion, differential diagnosis, and prognosis.

Precocious Menstruation.—Dr. G. P. Gengebach, of

Denver, reports a case of this in an infant, and gives a

summary of the literature, pointing out that physiological

factors may be disturbances of the ovaries, ad-

renals, thyroid, pituitary, or pinal glands. In his own

case the cause was not determined. No treatment for the

case was given.

Clinical Report and Post Mortem Findings in the

Case of a Child Dying from Acute Nephritis.—Dr. H.

McClanahan, of Omaha, reports this case. The

heart showed disease of the tricuspid and mitral valves, with almost complete obliteration of the outlets. The infant was

burned, or inguinal hernia, as shown by the postmortem

findings. During life the red blood count was eight millions, and the polycythemia was probably physiological, to com-

pensate for the cardiac disease.

The Hospital Management of Contagious Diseases.

—Dr. L. Robertson, of Madison, Wis., describes a system of so-called aseptic nursing. Many cases com-

monly considered suitable for isolation are kept in

the open wards of the provident hospital without spread of

infection. Contact infection between patients is elimi-

nated. He concludes his paper with statistics showing the frequency of "cross infections."

Federal Children's Bureau: The Law, the Organiza-

tion, the Scope of Its Present Work.—Dr. Julia C.

Lathrop, of Washington, D. C., explains that this bureau

was established to gather statistics relating to all phases of

child welfare. It also distributes educational literature,

and is now making studies to determine the best civic

measures to promote the health of children. The speaker

makes a plea for a nation-wide registration of births and

for the support of the medical profession. At present

the infant death rate is decreasing in the cities, but increasing

in rural districts.

The Etiology of Artificial Feeding; a Plea for the

Study of Breast Milk Problems.—Dr. H. Lowenburg,

of Philadelphia, states that there are two causes for the continuance of breast feeding: 1. Psychic.—Fear on the

part of the mother of inability to properly nourish her

child or selfish desire for pleasure. 2. Economic.—The

mother being obliged to earn a living. Vomiting, diarr-

hea, colic, or fretfulness in the infant are not indications

for weaning; neither is mastitis, unless the breast is dis-

charging pus from the nipple. Too much stress is laid on

artificial feeding, and too little is taught of the proper

management of breast feeding. He believes that every

mother can nurse her baby if she is willing to do so, pro-

vided that she has proper surroundings and proper care.

All obstetricians should be breast feeding enthusiasts. The

movement has contributed for summer camps, free milk, day

nurseries, and hospital feeding. He believes that if given to worthy mothers to enable them to continue nurs-

ing. He thinks the State should, if necessary, appropriate

funds for this purpose.

Joint Section of the Section in Diseases of

Children, with the American Association of Medical

Misfits.

Certified Milk.—Dr. T. C. McClave, of Berkeley,

Cal., reviews the history of the development of the conce-

ption of certified milk, and of the standards required by

the American Association for its production.

The Cost of the Production of Certified Milk.—Dr.

Samuel F. French, one of the Chicago producers, dis-

cusses the cost, the possibility of reducing this, the narrow margin of

profit, and the just price the consumer should pay.
The Efficiency of the Medical Milk Commission, Graphically Illustrated.—Dr. H. L. Cott, of Newark, N. J., by means of charts, shows the greater degree of efficiency of milk production, with the expenditure of a given amount of activity, under the supervision of medical milk committees.

The Effect of Barn Operations upon the Germ Content of Milk.—Professor H. A. Harding, of Urbana, Ill., recounts experiments made to show that the condition of the walls and floors of stables, failure to clip cows, and the thorough raising of stable dust are not the chief factors in raising the bacterial count in milk. More important are the proper sterilization of milk pans, their care after sterilization, and the proper cleaning of the cow and the milkman's hands.

SECTION IN DERMATOLOGY.

Tuesday, June 17th.

Chairman's Address: Our Tendency to Fads.—Dr. Joseph Zeisler, of Chicago, in his opening address, comments on the way dermatologists tend to follow extremes in current ideas and methods of diagnosis. He centers especially the giving of salvarsan when not indicated, and the cutting down on a vein to give it; thus needlessly marking the patient for life. The too free use of various vaccines, and especially certain mixed vaccines, is condemned. The taking of a Wassermann test in many easily recognized skin diseases is also included in the chairman's list of fads.

Two Cases of Pemphigus Foliaceus.—Dr. J. B. Kessler, of Iowa City, after giving the description of typical cases of pemphigus foliaceus, and commenting on various well known points in the etiology, diagnosis, and prognosis, describes two cases which he has treated. The treatment employed, which was adopted after he had read of its being used successfully in pemphigus vulgaris, consists of large doses of quin, as high as ten grains every four hours, given over a period of several weeks. Both cases responded to this treatment in connection with bran or bran and compound creosote solution baths. One patient has relapsed, the other is still well after three months.

Doctor Pusey said he had seen a case get well, and remain so, with only bland local treatment.

Doctor Sutton told of obtaining a pure culture of Bacillus pyocyanes and treating successfully a case with a vaccine of this germ.

An Anomalous Case of White Spot Disease.—Dr. H. H. Hazen, of Washington, D. C., describes a case of white spot disease in which the spots seem to come under either of the two general classifications of morphone guttata and lichen atrophicus. He first made a diagnosis of morphone guttata in a patient showing numerous white atrophic scarlatin spots, but later, upon microscopic examination, concluded that evidence was present of a change resembling a type of lichen atrophicus. Treatment gave no results.

Radium in Skin Diseases.—Dr. Frank E. Simpson, of Chicago, in this preliminary report, describes the results of radium treatment in fourteen cases, including fifteen different diseases. Either cures or good progress was reported in nuxus, epithelioma, lichen planus and varicousus, verruca, lupus vulgaris, lupus erythematosus, blastomyces, keloid, ringworm, and psoriasis of the nails. He has found it especially of service in lesions around the mouth and lips where it is hard to give other treatment.

Discussion brought out the fact that while many men have obtained good results, many others have not, and as a result the prohibitive cost the gadget sentiment was that only a very few cases present special indications for radium treatment.

The Massive Dose X Ray Method in Treatment of Skin Diseases.—Dr. George MacKee, of New York, describes in detail by means of slides the exact method of giving a single large dose of X rays. This is done by means of measuring the rays qualitatively and quantitatively. The qualitative determination depends upon a given current in the milliamperemtre and ampereatre with a tube that tests up to number nine on the Holtsknecht scale; in the dosage is measured by the Holtsknecht scale with the Saboraud pastile. He holds that with this exact method fewer cases of dermatitis occur and that in treating ringworm of the scalp permanent baldness never results. By lantern slides the results obtained are shown in cases of eczema, scabies, morphea, scarring atrophy, and various dermatoses.

Neuromas of the Skin (with Lantern Slide Demonstration).—Dr. M. L. Heidingsfield, of Cincinnati, describes two cases of neuromas of the skin. Both occurred after injury and consisted of small tumors on the anterior surface of the thigh. One had a direct course of treatment by slight pressure. A diagnosis was first made of myoma, and he thinks that many cases of myoma would be correctly diagnosed neuroma if a biopsy were made, as the simple diagnosis of neuroma is confirmed the finding of nerve tissue. Treatment consists of extirpation.

Angioma Serpiginosum (Infective Angioma of Hutchinson); with Report of a Very Extensive Case.—Dr. Fred Wise, of New York, presents an elaborate description of this case, together with an illustration of previously reported cases. Then, three cases are described in detail, one of his own and two of Dr. Howard Fox.

Doctor Politzer, who made the histopathological examination in Doctor Wise's case, stated that out of twenty-three or twenty-four cases reported, probably only three or four were correctly diagnosed; showing that the condition is very rare.

Wednesday, June 18th.

At the opening session on Wednesday morning a number of cases were demonstrated by the local men, Doctor Sweitzer, Doctor Butler, Doctor Boreen, Doctor Freeman, Doctor Crume, and Doctor Irvine. Among the cases were: Lichen planus; psoriasis; Darier's disease in a four month old infant, whose illness had been diagnosed as psoriasis by Doctor Irvine, but which resembled at the time of demonstration more a seborrheic dermatitis.

Salvarsan and Profeta's Law.—Dr. A. Raggini discussed the recent work and literature to show the errors of Profeta's law, and described a case where a woman after having a syphilitic child bore a healthy one following salvarsan treatment; a few months later this woman had macerated patches and the child was infected with intilination of previously reported cases. Then, three cases are described in detail, one of his own and two of Dr. Howard Fox.

Doctor Buhman, who made the histopathological examination in Doctor Wise's case, stated that out of twenty-three or twenty-four cases reported, probably only three or four were correctly diagnosed; showing that the condition is very rare.

A Study of the Spinal Fluid in One Hundred Cases of Syphilis.—This paper was presented by Dr. M. F. Engman, Dr. Rudolph Buhman, Dr. Robert H. Davis, and Dr. E. D. Groham, of St. Louis. Doctor Buhman said two classes of cases are essential in cases of syphilis; thirty-six early (infected within two years) and sixty-four late. Counting as positive only those cases which give a positive serological test and a cell count higher than ten, the authors conclude that only a very small percentage of cases give this positive test when no symptoms of loss of the nervous system are present. The majority of their cases that give this positive test also show other diagnostic symptoms. The value of the test as a check for treatment was still marked, in that eighty-nine per cent were still positive after one years treatment. Ten cases of fluid is withdrawn and immediately a full dose of salvarsan injected intravenously, examination of the spinal fluid fails to show presence of arsenic, demonstrating the fluid is resilient to chemical infection.

Comparative Study of Antigens for the Wassermann Reaction.—Dr. H. R. Varney and Dr. F. W. Baeslack are the contributors. After a discussion of the various antigens used in Wassermann reaction, they describe an antigen used from a guinea produced in the testicle of rabbits by inoculation with the spheroids, which is an alcoholic extract made after the method of Citron. They could not find that the test was more specific with this antigen than with the other. Positives were obtained with florid scarlet fever and lepra serum as with the other antigen. In making a lucit test with this material a somewhat stronger positive reaction was obtained.
was obtained than with the old method. Doctor Baeslack said that he thought the Wassermann test might depend upon three substances, first a lipid, second a substance from the saprophyte, and third a substance from the effect of the saprophyte upon the tissue.

A Study of Skin Diseases among the Indians of Oklahoma.—Dr. Everett S. Lain, of Oklahoma City, Okla., has made a very interesting study of skin diseases in the Indian children of the State of Oklahoma, with a comparison of the cases. Out of 3,500 cases, 1,000 were carefully examined. Tuberculous glands of the neck were found more frequently than any other disease, some 298 positives. The next most frequent was pityriasis capitis occurring in 227 children, and these practically all children going to school, and using a comb and brush. Acne and verruca were the next most common. Ringworm was quite rare and no cases of psoriasis, pellagra, alopecia, erythema multiforme, or scabies were found, also no cases of atopic dermatitis. A surprisingly small amount of lues was found, only forty-six cases. There was an absolute immunity to most toxic plants.

The Newer Cutaneous Mycose.—Dr. Ernest Dwight Chipman, San Francisco, after going over the diagnostic points of the pathogenic fungi, concludes that more study should be put on this work by dermatologists. He is inclined to think there is some difference between the blastomycosis and the granuloma coccidioides of the California cases and the children, and that these pathogenic fungi should be carefully examined and cultures made. Fewer cases would then be missed.

Cutaneous Affections of Childhood.—Dr. Alfred Schalek, Omaha, thinks that troubles with metabolism and errors in feeding are related to many skin conditions in children, and that there has been a considerable difference in the general condition of children with severe skin lesions who should be placed in the hospital. Local treatment should not be neglected, the importance of this is demonstrated by the fact that many cases of very faulty feeding and hygiene are observed with a lessening of the lesions.

Empiricism in Dermatological Therapeutics.—Dr. M. L. Ravitch, Louisville, Ky., makes a plea for more specific therapy. He found as high as seventy drugs being suggested for the treatment of one disease in several text books and considers that much more careful attempt should be made to get at the actual relation between the disease and the therapy, and to use then a given drug for its specific indication.

Primary Sarcoma of the Lower Lip.—Dr. A. J. Markley, Denver, comments on the few cases in the literature of primary sarcoma of the lip. Only a few cases occurring on the lower lip in a man, sixty-five years old. Clinically it was not diagnosed, as it had all the appearances of an epulis. Owing to the importance of the necessary treatment of the case a specific case should be made in these cases before treatment is instituted. In his case six months after extirpation a nodule was found on the neck which was promptly excised; since then no other recurrences have appeared. Dependence should not be placed on lymphatic invasion to diagnose the sarcoma as it may also occur in small round cell sarcoma.

THURSDAY, JUNE 10TH.

Relation of Diabetes to Various Dermatoses.—Dr. Burnside Foster, St. Paul, calls attention to the number of dermatoses connected more or less intimately with diabetes, stating that the dermatologist could frequently be the first to suggest diabetes. The most common skin complication of diabetes is the pruritic, a rash which is less likely for the furuncles and carbuncles which are so frequently seen. Genital irritation of the sugar laden urine also occurs frequently. Treatment should be directed toward the diabetes.

Idiopathic Atrophy of the Skin with Report of a Case.—Dr. H. G. Irvine, Minneapolis, presented a case with his paper showing very marked atrophy of the skin of the arms and legs and extending a little on to the trunk. The inflammatory stage of the disease was well shown or the lower legs. Comparatively few cases have been reported in the United States, and many of those very meagerly. This is undoubtedly a distinct disease and cases of secondary atrophy and scleroderma should be excluded. No cases have been satisfactorily preceding the diagnosis, but two cases have been reported as recoveries.—Doctor Sutton, Doctor Pusey, and Doctor Heidingsfeld discussed the paper.

Mycosis Fungoides Following Psoriasis.—Dr. Howard Fox, New York, observes that although there are many cases in the literature where some mention has been made of psoriasis and psoriatic-like lesions occurring early in the disease, Fox was able to find only two cases that he considered actually preceding the diagnosis of mycosis fungoides. This case was seen by several dermatologists, and there appears to be no doubt as to the diagnosis of both diseases. Two interesting points were brought out, there was no itching which is unusual, and patient was not alcoholic but alcohol is not supposed to play any part in the etiology many have been alcoholics.

SECTION IN OPHTHALMOLOGY.

TUESDAY, JUNE 17TH.

Chairman's Address.—Dr. Hiram Woods, of Baltimore, calls attention to the sociological aspect of medicine and the need of a scientific approach to ophthalmology, and recommends that a committee be appointed to report on the subject.

Physiological Optics the Basis for Teaching Clinical Ophthalmology.—Dr. Albert Foster, of Boston, urges the more extensive training of the ophthalmologists on the line of physiological optics. Physiological optics so permeates the whole of ophthalmology that no part of that large field can be mastered without a good understanding of this subject. Nowhere in this country has there been offered a systematic course in physiological optics founded on laboratory work and covering all the main subdivisions of the subject in reasonably adequate fashion. Courses in physiological optics should include not only the dioptric relations of the eye but also its functional movements, light sense, and problems of illumination, color sense, visual fields, and all other subdivisions of the subject. Doctor Lancaster then speaks of the value of a diploma or degree of some sort as a guarantee that its holders have had adequate training before they join the ranks of specialists in any of the special fields of medicine.

Some Modern Viewpoints with Regard to Glaucoma.—Dr. Robert Sattler, of Cincinnati, discusses these questions: Should glaucoma simplex and acute inflammatory glaucoma be assigned to separate categories? Is glaucoma a lymph or blood stasis, or is it a sudden choking off of both and retention of greater blood volume? Is the increase of blood volume due to the application of intraocular chemical forces? Is increased intraocular tension a distinctive feature only, which chronic and acute inflammatory glaucoma have in common? He then discuses the modern views of normal tension.

Experimental Study of Intraocular Pressure and Ocular Drainage.—Dr. Mark J. Schenckberg, of New York, states that the intraocular pressure, measured by the Schiötz tonometer, records three factors. The steady application on a normal eye of a weight gradually reduces the intraocular pressure. This diminution is mostly due to the expression of intraocular fluid through certain channels outside the eyeball. The rapidity of reduction, as measured by the tonometer, is greatly increased on an inflamed eye, constitutes its rate of ocular drainage. The author's study of ocular drainage has revealed: 1. In a normal eye a gradual reduction of intraocular pressure if the tonometer is applied for a certain number of seconds. 2. A variety in the rate of ocular drainage, not only in different eyes, but also in the same eye, at different periods. Changes of intraocular pressure in one eye, sometimes followed by similar changes of intraocular pressure in the other eye. 3. The possibility of some kind of action starting from distant organs and influencing the intraocular pressure. 4. The probability that the extrinsic muscles play an important role in the various normal fluctuations of intraocular pressure. 5. Different rate of ocular drainage in glaucomatous eyes from that of normal eyes. In the discussion on these three papers, Doctor Jones,
of Cumberland, said he had had good results with subconjunctival injections of 1/1000 cyanide of mercury and sodium.

Doctor Alt, of St. Louis, said he thought the chemistry of the blood had some relations to glaucoma, and he gave large doses of calcium chloride with fairly good results.

Doctor Fox, of Philadelphia, said he had had five or six cases of congenital glaucoma, and believed that the condition was due to a lack of development; there being no canal of Schlemm. In cases of chronic interstitial nephritis there is often a plus tension; so in conditions where there was a high blood pressure. In these cases he always reduced the blood pressure as much as he could before operating, and then found that evisceration would work where it had not previously done. He would then do an iridectomy. He performed the Elliott operation in a great many cases.

Doctor McKeynolds, of Dallas, recommended the Elliott operation with some modifications.

Doctor Greenwood, of Boston, recommended the Le- grade operation, and said he had found a marked improvement in the field as a result. He had only lost one eye in twenty-five operations.

Doctor Parker, of Detroit, said he thought the eye posterior sclerotomy and paracentesis of the anterior chamber is the operation most often used, and often recommended. The operation is supplemented by other procedures. Sclerectomy appears to be the operation which best meets the requirements. De Vincenzi's operation also appears to be well adapted to the conditions present. He gives an analysis of replies received to a circular letter to surgeons throughout the country. Some form of sclerectomy was the only procedure which gave satisfactory results to the majority of surgeons employing it. Histological study of the eye with congenital coloboma showed an absence of the canal of Schlemm and a failure of the aqueous humor to flow to the posterior chamber by a proliferation of connective tissue which represented the pectinate ligament. A case of a child born without eyes and another case of infantile glaucoma were shown. The glaucoma had been trephined with good results.

Equivalent Values in Spectacle Lenses.—Dr. William E. Shahan of St. Louis, says the advantages of menis- cus lenses are largely lost because their effective values differ from those of trial case lenses. Compensatory computations for these discrepancies can be made by calculating the advancement of the second gaussian points and the posterior poles of the lenses from the plains of their rims, and finding the corresponding equivalent diopter values. A number of points can be calculated for the equivalent of each trial lens from the limbus, and a curve representing the change in the prescription written without any laborious computation.

Symposium on Trachoma.

Trachoma, Its Prevalence and Control among Immigrants.—Dr. John McMillen, of Washington, D. C., of the United States Public Health Service, speaks of trachoma as a chronic, communicable disease, often causing disastrous results. Diagnosis and prognosis is the most troublesome subject with which the medical examiner dealing with the disease is confronted. Trachoma was classified in 1880 as "dangerous contagious disease" by the federal government. Despite the fact that the steamship companies maintain an inspection service abroad, many hundreds of cases are found annually among immigrants, the majority of them from Russia, Austria, Hungary, Turkey, Armenia, Syria, and Greece. Any modification of the present classification by the government would mean the addition to our population of thousands of aliens suffering from trachoma, whose immigration to this country is prohibited. Trachoma is an important public health problem.

Trachoma among the Indians.—Dr. J. W. Schres- chewsky, of Washington, D. C., states that 30,000 In- dians in the United States were examined, with the result of finding that over seventeen per cent were suffering from trachoma. The incidence of the disease varied from nearly seven per cent in Oklahoma to 0.2 per cent of the Indians of New York State. The disease was found to be most prevalent among the inmates of Indian boarding schools, and least prevalent among reservation Indians. All grades of the infection were seen. Its prevalence among Indians is due to their ignorance of hygiene and sanitation. The percentage of Indians suffering from visual defects due to trachoma is high, and the Indians are likely to prove a means for the widespread dissemination of trachoma in the West. Energetic efforts should be directed toward limiting the spread of trachoma among the Indians and attempting its eradication among the younger generation.

Trachoma among the Mountaineers of Eastern Ken- tucky: Illustrated by Lantern Slides.—Dr. A. Stucky, of Lexington, Ky., states that in this region the number and gravity of cases of trachoma coming to him from the mountains of eastern Kentucky in the past twenty-five years led him to make a trip of investiga- tion on muleback through the backwoods of the mountains. He found the people (genuine Anglo-Saxon) and how they live. There are unmistakable evidences of the infectiousness and destructiveness of the disease, and an appalling number of cases with destructive sequelae of trachoma (pannus, en- trapment, trichiasis), general ulceration with perforation and symblepharon. The solution of the problem of eradi- cating the disease is difficult: the Kentucky State Board of Health has been unable to adequately cope with the condition for financial reasons. Lantern slides showed the contacts with trachoma, their homes, and how climes are conducted in the tent and cabin hospital.

Metastatic Ophthalmia. Report of Three Cases, One of Which Resulted in Recovery of Vision.—Dr. Wil- liam H. Wilder, of Chicago, describes these three cases. In one of the cases the patient had a long history of cryptogenic character, thrombosis of one leg, parapiditidis and cystitis: and also metastatic ophthalmia in left eye, followed by similar inflammation in right. Bacillus coli communis in urine, Staphylococcus aureus in blood. Disease from terminal pneumonia, in left eye, of young woman aged twenty-five, suffered from tonsillitis, otitis media, pneumonia, synovitis of wrist and knee, and finally metastatic ophthalmia of left eye. Inflammation severe, but eye did not suppurate. Virulent streptococcus in tonsils, ear, and eye. General recovery with tuberculosis of sulcus. The third patient, a girl of eighteen, had had diphtheria followed by streptococcus infection of the tonsils. Sudden loss of vision of both eyes with violent uveitis, severe pain, and chemois. Ultimate subsidence of inflammation and recovery of normal vision in both eyes. The speaker then takes up the general consideration of the disease, the symptoms, etiology and prognosis: referring particularly to the grave prognostic significance of the affection in general septic conditions.

In the discussion, Doctor Greenwood, said that five years age they had in Boston, an epidemic of cerebral spinal meningitis, in which metastatic stages developed in a great portion of the cases in which optic atrophy occurred. Most of the patient died.

Doctor Casy Wood, of Chicago, reported a case of pregnancy where bilateral metastasis developed. He also stated that most bilateral metastasis of this kind was fatal, not only to sight but to the patient.

Doctor Jackson, of Denver, reported two cases of metastasis following pneumonia, in which panophthalmitis developed.

Doctor Alt said that panophthalmitis of cerebral spinal meningitis is not a metastatic, but a direct infection of the nerve sheath.
The Diagnostic and Therapeutic Uses of Tuberculin in Ocular Diseases, with a Review of Some of the Claims Made for Its Use, by Dr. S. Howard Davis, of New York, speaks first of tuberculin reactions—their nature, the factors comprising them, and the part they have performed in establishing the great frequency of tuberculous infection in the human race. Next immunity is considered, the immunity of the tuberculin or tuberculin allergy, one of the most important tuberculin preparations.

The author gives a review of some of the diagnostic and therapeutic results obtained by the use of tuberculin in the treatment of ophthalmic diseases, together with a report of personal experiences.

Phlyctenular Ophthalmia and Episcleritis: A Study of the Bearing of the Newer Research on their Etiology as the Basis of a Scientific Therapy.—Dr. WALTER, of Chicago, states that this study is an attempt to harmonize the theories of the tuberculin and phlyctenular theories and to etiology and tends to show their interdependence. He divides the theories into (a) ectogenous theory, which concerns bacterial invasion from without; not proved; (b) endogenous theory, embracing, 1. patients with phlyctenular conjunctivitis, beginning with small doses and increasing every five or seven days. The condition cleared up under the first treatment, but after a lapse of treatment, it returned. Dr. CHARLES SKATT, Jr., of Minneapolis, showed a so-called cased tuberculous scerosis, which he had treated with tuberculin giving some sixty-four doses. The condition cleared up afterward under the first treatment, but after a lapse of treatment, it returned.

The Temperature of the Conjunctiva.—Dr. LUCIEN HOWE, of Buffalo, states that if two thermo couples are placed in a circuit and one heated or cooled more than the other, it is possible to register in a galvanometer. If one such couple is introduced into the conjunctival sac, and another into the mouth, the difference in temperature is registered by the galvanometer. The coupled described measures easily the degree of elevation obtained by these measurements. The temperature of the cul-de-sac near the outer or inner canthus is from about 0.3 to about 0.4 C. lower than that of the mouth; the temperature of the conjunctival sac is an average of 0.3 C. lower than that of the conjunctiva. It is obvious that the thoero couples described will prove of value in indicating changes of temperatures in the globe itself, and metabolic changes in eyestain.

The Topical Diagnostic Value of the Hemipnic Pupillary Reaction and the Wilbrand Hemianopic Prism Phenomenon with a New Method of Performing the Latter.—Dr. CLIFFORD B. WALKER, of Boston, describes the methods of performing the hemipnic pupillary reaction test, and the method of performing the Wilbrand hemianopic prism phenomenon test. He gives results on twelve cases in the neurological surgical clinic of Dr. Harvey Cushing summarizing discussion: Hemipnic pupillary reactions: 1, possible errors; 2, the Wilbrand hemianopic prism phenomenon test: 3, clinical hemianopic prism phenomenon: 1, possible errors; 2, the factor of intelligence or power of observation; 3, pseudofixation. Conclusions: Hemipnic pupillary reaction: 1, nothing noted in disagreement with the work of Hess; 2, the possibility of a hemipnic pupillary reaction within the central pupillomotoric area; 3, concentric movement psychic reflex; 4, clinical failure. Wilbrand hemianopic prism phenomenon: 1, diagnostic value; 2, natural degeneration of ocular reflexes will turn disturb the labyrinth and produce vertigo. Whether all of the vertigo produced by eyestain is a reflex disturbance of the eighth nerves, or whether possible dizziness may be produced by disturbances of the higher centres without interposition of the lower centres is undetermined.

Preventable Blindness.—Dr. HENRY COPLEY GREENE, of Boston, field agent of the Massachusetts Commission for the Blind, presents reports of investigations made by the Commission, and deductions therefrom.

Election of Officers.—Dr. Frank S. Todd, of Minneapolis, was elected president for the current year, Dr. T. C. CUSHING, of New York, was re-elected vice-president, Dr. E. WAYNE WAGNER, of Chicago, secretary, and Dr. William Zentsmayer, of Philadelphia, treasurer. The following were elected to the Board of Trustees: Drs. George S. Derby, of Boston; Hiram Woods, of Baltimore; Albert E. Bulson, of Fort Wayne, Ind.; Adolph A. and Louis L. Davis, of Minneapolis.

Ocular Vertigo.—Dr. ALLEN GREENWOOD, of Boston, states that a good deal of vertigo of moderate severity is undoubtedly caused by the eyes. Experience will show that vertigo is the consequence of trouble with the eyes, and that the vertigo is caused by movements of the eyes or by rotation of the eyeball. The vertigo produced by means of rotation and thermal tests will produce rotatory nystagmus, and it is reasonable to suppose that vertigo is caused by movement of the eyes which calls for unusual and unnatural movements. When a patient says that he is always dizzy, all dizziness must always be watched.

Is the Percentage of Myopic Eyes Diminishing?—Dr. SAMUEL D. RISLEY, of Philadelphia, claims that his paper is a continuation of the statistics set forth in an article on school hygiene, showing the steadily diminishing percentage of myopia, as a consequence of the careful correction of the anomalies of refraction by ophthalmic surgeons. These figures are given to demonstrate the truth of the claim made in a paper of the examination of the eyes of school children in Philadelphia, published in the Medical News. It was there shown that the increase in myopic eyes during school life was due to the congenital visual defects with which children entered on their school work, rather than on faulty refraction in the school. The present study is undertaken to discover whether the percentage of nearsight has continued to be the same as it was in 1894.

The Asthenopia of Muscular Imbalance.—Dr. HOWARD P. HANSELL, of Philadelphia, refers first to the well-known relation between refraction and asthenopia. Then the less well considered relative accommodation and convergence as a cause of asthenopia from persistent or changing dioptric errors of accommodation, and the relation of dioptric errors of accommodation to ocular movements, or oculomotor disturbances, is described, and attention is particularly directed to frequently changing axes of astigmatism, power of accommodation and of convergence in presbyopia, depending less on ocular conditions than on the general health and individual peculiarities of the nervous system. Asthenopia of muscular imbalance, it is said, does not depend on one muscle, but on the simultaneous and harmonious or inharmonious action of the entire ocular musculature and its nerve connections.
Apparent Esotropia and Its Relation to Convergence Insufficiency.—Dr. H. B. Lemere, of Omaha, says that apparent esotropia is the condition of ocular imbalance in which there is an esotropia in the distance and convergence insufficiency for near vision. The convergence insufficiency is the true cause of the trouble, and the symptoms are relieved when convergence power is strengthened either by operation or exercise. The operation is not a rank operation, some opinion.

Blepharochalasis. Report of Two Cases with Microscopical Examination.—Dr. Walter Baer Wedler, of New York, states that blepharochalasis is an atrophic condition of the lower eyelids with pouchlike formation of tissue in the eyelids. It occurs most often in young girls, appearing usually at the age of fourteen, and always limited to the upper lids. This condition must not be confounded with ptosis adiposa. There are no subjective symptoms, but the deformity and disfigurement make them seek advice and treatment. The skin of the upper lids is slightly pinkish red, and smooth in the early stage of the disease; later there is a distinct atrophy of the skin of the lids, and countless fine lines appear. The superficial veins become more conspicuous as the stretching and atrophy of the skin increase. The skin and subcutaneous tissues hang down in a baggy, puckish-like mass, the lids seem to be lower than usual, but there is no true ptosis of the lids present. As regards treatment of this condition, excision of a portion of the mid-portion of the lids is the operation of choice, in the only thing that has given any satisfactory results.

Postcatact Extraction Delirium. Report of Eleven Cases.—Dr. Walter R. Parker, of Detroit, gives a history of eleven cases of the new condition, following cataract extraction. He attributes the new condition to the theories of the etiology. While all agree that heredity plays an important part, and that weak patients subject to the operation or disease preceding is only the exciting cause, there is no agreement as to the class of cases with the condition. He believes that the character of the operation and the psychosis, and no single form of mental disturbance is characteristic of postoperative delirium. Eleven cases are reported and the following observations made: 1. The delirious state was the same every time on examination. 2. No case showed marked signs of mental disturbance while under observation. 3. One case showed possibility of infection from an old cystitis. 4. The urine was normal in nine cases, not recorded in two cases. 5. Cocaine was administered in two cases. 6. Cocaine poisoning is eliminated.

In the discussion, Doctor Jackson, of Denver, reported several cases of delirium after miotics. He thought that the case reported by Doctor Wedler was caused by a greenish tinge in the eyes of the patient. Doctor Greenwood, of Boston, thought the condition due to a mental shock. He tries to do the operation in the home. Doctor Wescott, of Chicago, reported one case, seventy years old, with arteriosclerosis. Delirium developed on the third day, with an attack of delirium, and was killed. He believed that the delirium is due to a senile condition. Doctor Risley, of Philadelphia, reported two cases. He never gives morphine after operating, but rather small doses of hyoscyamus. He always puts his patient on a tonic of night morsica, tincture of gentian, and compound tincture of chinchor. He often lets them smoke. Doctor Black, of Denver, gives one eighth grade of morphine one hour before operation, as he feels perfect mental rest. He lets him sit up the next day.

Surgical Treatment of a Certain Type of Penetrating Wounds of the Sclera by a Double Conjunctival Flap.—Dr. Lee Masten Francis, of Buffalo, says that the use of surgeons of conjunctival flaps has been considered, as well as others, to cover penetrating scleral wounds, a well-established surgical principle. He explains the reasons for closing all scleral wound of three millimetres or more with scleral sutures in addition to conjunctival plasty. In wound of lesser dimension, a limit of proper elevation of the conjunctiva, two flaps may be made of the conjunctiva, which will serve the double purpose of drawing the wound edges together and providing a firm apposition. The conditions of the double flap are: 1. Because of the traction exerted by the two flaps, the scleral wound lips are held in firm apposition. Consequently relatively large scleral wounds may be rapidly and safely closed without stitching the sclera. 2. The resulting scar is thinner, firmer, and more unyielding. 3. Two layers of sound conjunctiva protect the contents of the globe from outside infection.

Primary Lues of the Bulbar Conjunctiva.—Dr. Charles Nielson Spurtt, of Minneapolis, believes that from six to seven per cent. of all chancres are extra-genital. About the eye, the margins, and skin of the lid are the most, and the bulbar conjunctiva and limbus the least frequently involved. The author reports the case of a nurse girl, twenty-seven years of age, who had the care of a syphilitic infant. Twenty-one other cases have been found in the literature. All except one were in adults. There were five nurse maids and two physicians. Right eye involved ten times, left six, not given six. Eight were studied on the nasal and temporal sides; four to the inferior; four on the limbus; two not given. Mode of infection: 1. Direct, as by kissing, coughing, splashing of fluids, etc. 2. Indirect. Infection carried by the hands.

Mediate, instrument, etc. Symptoms: No pain noted, except when chance is on limbus. Diagnosis: Marked chemosis, with hard indurated area with a central ulcer, and enlargement of preauricular gland.

SECTION IN NERVOUS AND MENTAL DISEASES, TUESDAY, JUNE 17TH.

Chairman's Address: Neuroasthenia and Increased Susceptibility to Emotion.—This paper by Dr. H. T. Skirving, of Denver, is based upon the observations and reports of 1,000 carefully studied cases. He excludes from the list of neuroathenics those cases where the nervous condition is due to some previous existing organic disease which, being primary, would be a reason for the condition, but it is also necessary to distinguish those symptoms which, though ordinarily due to some underlying physical condition, may be due to the neuroathenics. The neuroathenics is not due to overwork, but to a lowering of the emotional threshold. While this condition is a lowering of the emotional disturbance maintains a vicious circle of fatigue and emotional excitability. Clearly the treatment must rest in the re-establishment of this emotional stability. It must include an attempt to displace the false ideas, and requires a sympathetic understanding of the patient on the part of the physician, as well as a thorough examination. Opium is recommended as the most useful drug available.

Dr. A. A. Ball insists on restricting the field of neuroasthenia further, and ordinarily looks upon depression as suggesting something more than neuroasthenia. He also considers a greater degree of fatigue in the morning than in the evening as suggestive of depressive conditions.

Premonitory Auras in Alcoholic Neuroses.—Dr. T. D. Parshuram, of Milwaukee, claims that alcoholism and inebriety. The latter bears a close relation to epilepsy, and auras are common. These are of varied character, sometimes physical and sometimes psychic, which he describes at some length. Alcoholism lacks these auras, but in both, the mechanism of the condition is the same. The treatment the author recommends excessive hydropathic and eliminative measures and mental suggestion.

Multiglandular Syndromes and the Nervous System, with Lantern Slide Demonstration.—Dr. John H. B. Orsay, of Chicago, refers to our limited knowledge concerning the action of the ductless glands and to the relation between the disturbed action of these and various nervous phenomena. Lantern slides are shown from several cases where the ductless glands and nervous were all probably dependent upon some disturbance of the ductless glands. Treatment is largely experimental and more or less unsatisfactory, but one case of osteomalacia is cited where castoration was followed eventually by cure.

Diagnosis, Prognosis, and Treatment of General Paresis.—Dr. C. R. B. Ball, of St. Paul, discusses the changing views concerning the relation of syphilis to general paresis from the time, in 1857, when syphilis was first definitely known to be the cause. The case was looked upon as the chief cause, and to a more recent period when the doctrine of "no syphilis, no paresis" is rather generally held. We have been slow in coming to the conclusion that the primary cause is not that of general paresis, and because of the general failure of antipsycotic therapy in the latter disease. Noguchi's recent findings mark a distinct change in our view of the pathology of the so-called metasplaphtic conditions. The speaker looks with disfavor upon the com-
mon tendency to regard all cases of paresis as hopeless. Ten per cent. undergo more or less prolonged remissions. He recommends injection of sodium nucleinate and sal-vasan. Under this treatment Nonne's reactions were decreased but did not disappear. The clinical condition also improved.

**Pathological Findings in Insanity; Illustrated with Lantern Slides Showing Gross and Microscopic Lesions.**

-The demonstration of Dr. H. D. Valin, of Mankato, Minn., consists largely of lantern slides illustrating a variety of pathological conditions found in insane persons.

**Tumor of the Hypophysis in Acromegaly; a Clinical and Post Mortem Report, with Photomicrographs.**

-Dr. Julius Grinker, of Chicago, reports that this patient showed the ordinary symptom of acromegaly, along with epileptic attacks and, later, mental disturbances with unce- natre. However, in the author's opinion, the most significant point is the author's belief that the post mortem examination showed a large adenoma pushing up the optic chiasm and bilateral hydrocephalus.

**Symptomatology of Multiple Sclerosis.**

-Dr. L. H. Mettler, of Chicago, says that in the eyes of some this is the most common of organic nervous diseases. He prefers the collection of the two conditions in railway employees. In order to make a positive diagnosis he believes that the post mortem findings are necessary unless one is dealing with a very typical case, such as of the Charcot type. In view of this, it is important to differentiate the exact frequency of the affection. One must especially distinguish from instances of disseminated encephalomyelitis. The most important signs of multiple sclerosis are: A certain type of optic atrophy, intention tremor, speech disorders, and signs of motor in- volvement in the cerebral palsy. Dr. C. D. Camp believes that the study of the cerebrospinal fluid is very important in the differential diagnosis of these conditions.

-Dr. J. Grinker states that with the newer methods, the Wassermann test never gives a positive reaction in multiple sclerosis.

**Epilepsy and Paresis in Railway Engineers and Firemen.**

-Dr. C. D. Camp, of Ann Arbor, Mich., says that in questioning the medical officers of railway and motor companies he received little or nothing given. In a few instances epilepsy in enginemen and firemen, though his own experience shows that the coincidence is not rare. He reports four cases seen recently and several from medical literature. Suggestions are offered in the paper for the detection of the two conditions in railway employees.

-At the close of the discussion the following resolution was passed: "That the secretary of the section be asked to communicate with the publicity bureau of the associa- tion in order that it be known that this disease is a dangerous for epileptics and paretics to be employed on railroad trains and that means be taken to prevent it."

**Two Cases of Circulatory Disturbances of the Brain.**

-Dr. C. Eugene Riggs and Dr. E. M. Hammer, of St. Paul, report these clinical cases, with the results of a post mortem examination. A description of the clinical phenomena is presented. In the first case the syndrome appeared to be that of occlusion of the posterior inferior cerebellar artery, and in the second, at necropsy, a ruptured aneurysm, before the division of the right posterior cerebral and posterior communicating artery, was found.

**The Conception of Homosexuality: Its Theories, Psychological Mechanisms, and Treatment.**

-Dr. A. A. Ball, of New York, reviews the theories as to the origin and development of homosexuality, and discusses its rela- tion to degeneracy. Illustrative cases are given, and the therapy with its results fully gone into.

**Can Rabbits Be Infected with the Virus of Syphilis Despite the Inability of the Virus to Multiply in Rabbits?**

-Dr. C. E. Riggs, of St. Paul, has succeeded in infecting two rabbits directly from the blood of two cases of general paralysis and in trans- mitting the disease from one of these rabbits to two other rabbits, and from the other of the original two rabbits to four other rabbits. The spirochetes have the indenti- cal morphology of the Treponema pallidum in tissue emulsions, India ink, and Gram's stain. His studies have shown that the ringlike bodies first described by Noguchi, from which spirochetes seem to develop. Further studies in morphology and special staining of the Treponema pallidum in pure culture may enable physicians to recognize these forms microscopically in the blood and spinal fluid of syphilis.

**Exud.—Dr. Encephalitis Benigna of Indian Disorders, discusses the condition of the brain in exuda- tive encephalitis, including the grosser and finer changes so far as they have been observed, and also reviews the clinical signs presented and the differentiation of this from other cerebral conditions.

**ANNUAL REPORT OF THE DEPARTMENT OF HEALTH.**

-Further Notes on the Pneumothorax and Pneumatisis Conditions.—Dr. Ross Murdoch, of Los Angeles, in this paper makes an attempt to define certain types of physical and mental constitution in which a distinct mental disease is likely subsequently to develop. The physical signs are: Evidences of ready fatigue, fullness of the eyes, twitching of the fingers, and full abdomen—all in con- nection with mental apathy.

-In the discussion, almost all the participants agreed that, with careful methods of operation, it is possible to foretell an oncoming mental breakdown, and, in some of these cases at least, to prevent the development of a full fledged attack. One of the speakers, Doctor Mettler, said that while he realized the importance of investigating the mental conditions in childhood, he thought there was some danger of meddlesome interference in the training of children.

-A motion was finally adopted that a committee be ap- pointed, to report in one year, as to methods by which this section may be helpful in the question of the hygiene of childhood with reference to nervous and mental dis- ease.

**A Division of the Auditory Nerve for Persistent Tin- nitus and Vertigo.**

-Dr. C. H. Frazer, of Philadelphia, has found a large for the division of the auditory nerves. One of the last of these to come under the care of the surgeon is the auditory nerve. He considers par- ticularly operations on the intercranal portion of the nerve. When tinnitus is combined with vertigo we should operate on the nerve, rather than on the end apparatus. As a rule, the patient is already deaf on the affected side: consequently the effect of the operation on hearing is not to be considered. A small portion of the occipital bone is removed. The cerebrospinal fluid is withdrawn. In the case quoted by the author the result was very gratifying, and the tinnitus wholly disappeared.

**Occlusion of the Posterior Inferior Cerebellar Artery; Report of a Case.**

-Dr. G. W. Robinson, of Kansas City, remarks that syphilitic lesions of this condition in literature. He reports a case, with a very careful analysis of symptoms, and a summary of the characteristic features of the lesion.

**Demonstration of Lange's Coldtest of the Cerebrospinal Fluid.**

-Dr. R. E. White, of Chicago, presents the result of a study of the cerebrospinal fluid in 150 cases. This study showed the method to be of great value in diagnosis. Blood in the cerebrospinal fluid will interfere with the value of the reaction, just as it does in the Nonne test. The technic of the examination is not particularly difficult, but extreme care is necessary in pro- ducing the gold solution. All syphilitic lesions react with a maximum intensity in dilutions one to forty and one to eighty. Nonsyphilitic lesions a maximum intensity in dilutions of about one to 640.

**Certain Nervous Phenomena in Pernicious Anemia.**

-Dr. C. E. Riggs, of St. Paul, states that in several cases seen by him the nervous phenomena have long preceded the anemia, and that the prolapsus of the umbilical artery is found in the blood. The cord symptoms are much like those of ataxic paraplegia, and, in some instances, distinct mental abnormalities, such as those of dementia paralytica, were observed. In the clinical cases are cited and the literature re- reviewed. Salvarsan intravenously is recommended in the treatment.

**SECTION IN GENITOURINARY DISEASES.**

-TUESDAY, JUNE 17TH.

**SYMPOSIUM ON DISEASES OF THE KIDNEY AND URETER.**

-**A STUDY OF THE NORMAL KIDNEY, ITS PELVIS AND URETER; WITH STEREOTYPIC VIEWS.**

-Dr. S. B. Chilis and Dr. W. M. Sweitzer, of Denver, state that the object of work performed by them in studying ten cases as nearly normal as possible was twofold: First, to attempt to establish a
normal kidney, pelvis, and ureter; second, to note the appearance of the pelvis with the x ray. Young patients were selected, and wherever any fault could be found with the urine it was rejected. Pictures were taken in the lying and standing positions. Collargol was injected into the pelvis of the kidney by inserting catheters in the ureters, to a point when slight pain was produced. The following points were noted in the study: 1. The catheter usually entered the upper part; 2. the ureteral length is an important factor in the pathologic condition if there is any ptosis; 3. in sixty per cent, of the cases kinks of varying degrees were demonstrated; 4. the shape of the pelvis was determined. This was found to be pear shaped, quadrangular, kidney shaped, or instance bell.

In the lantern the shape of the pelvis and position of the catheter were shown. In the standing position the kidney is from 0 to 3.5 cm. lower than in the lying position.

Stereoscopic Views of Pathological Conditions of the Ureter and Kidney, with Methods of Examination, and Their Bearing on Diagnosis.—Dr. Transford Lewis, of St. Louis, shows upon the screen a number of x ray pictures of papilloma, malignant papilloma, anamalous sacculations, and stasis in the pelvis. In connection with these there was a description of cystoscopic operation which was done for the relief of the condition.

The Formation of a New Ureter: Experimental Study.—Dr. D. N. Eisenbrath, of Chicago, states that his experiments have been successful. He has removed portions of the bladder for transplantation, attaching them to the proximal and distal ends of the severed ureters. His attempts by using a section of an artery or a vein a segment of gut, failed. He has, however, discovered the possibility of having an epithelium which is accustomed to the presence of urine. Even though these experiments failed, he believes that eventually a successful method will be developed, based on the idea of free transplantation of a portion or the entire thickness of the bladder wall employed to act as a permanent bridge between the two ends of a severed ureter.

Implantation of the Ureter into the Bowel; with Report of Two Cases.—Dr. Carl Beck, of Chicago, reported two cases in which the implantation of the bladder into the bowel. The end of the ureter was made to project well into the lumen of the gut.

Symposium on Bladder Tumors.

Chairman's Address: The Present Status of the Diagnosis and Treatment of Tumors of the Bladder.—Dr. Hugh H. Young, of Baltimore, asserts that nearly all tumors of the bladder in persons over forty years of age are malignant in character. The first requisite in regard to treatment advised is removal, with a wide resection of tissue beyond the tumor. He advises the use of a twenty per cent, solution of resorcin painted over the surface of the tumor, and extreme care in handling the growth, during removal, in order to prevent implantation elsewhere in the mucosa.

Chronic. Cystitis in Women not a Disease.—Dr. George C. Smith, of Boston, from a study of ninety-eight cases at the Massachusetts General Hospital, concludes that in every case, carefully studied, the cause of the cystitis will be found to be in some lesion higher up in the urinary tract. These lesions include tuberculosis of the kidney, pyelitis, and pyonephrosis. He asserts that the cystitis is a secondary manifestation of one of these lesions.

The Transverse Incision of the Skin and Abdominal Fascia as a Method of Approach in Suprapubic Operations on the Bladder and Prostate.—Dr. Granville MacGowan, of Los Angeles, in this paper shows very clearly the advantages of this incision, inasmuch as there is less danger of infection of the suprapubic tissues. It also affords a better exposure of the bladder, and is followed by better drainage.

Radiological Studies of the Open Bladder, with Lantern Slide Demonstration.—Dr. E. O. Smith, of Cincinnati, presents an interesting description of the embryology and microscopic anatomy of the prostate, followed by an account of malignant growths in the gland. The symptoms and remedial effects of prostate are also discussed.

Radiographic Observations of Pus Tubes in the Male.—Dr. William T. Belshie, of Chicago, states that infection of the seminal duct may produce an abscess in the duct, or there may be recurring infection of the seminal
duct through the prostatic urethra. He advises drainage through either the vas deferens or the urethra.

**THURSDAY, JUNE 19TH.**

**Symposium on Diseases of the Testicle.**

**Operative Treatment of Undescended Testis.**—Dr. Arthur Dean Bevan, of Chicago, mentions the types of undescended testicles referable to anatomical location, and speaks of the dangers a patient with this anomaly is exposed to. He remarks that the testicles should be fairly large, etc. Next, he discusses the history of the operations, and describes the technic of what he believes to be the best method of procedure. He emphasizes the importance of saving the tunica vaginalis. The absence of one testis must be noted, and the so-called accessory testicle is frequently a case of diagnostic error.

**The Probable Embryonic Origin of Tumors of the Testicle, with Report of Two Cases and Lantern Slide Examination.**—Dr. A. C. Strokes, of Omaha, has prepared a number of sections showing the probability of the embryonic origin of these tumors. In some of the sections are clearly demonstrated cells of different types. He emphasizes the extreme malignancy of the tumors. Metastases of various kinds occur. He points out the probable evolution from the sexual cells of the testicle. Tumors of similar character are found in the kidney, ovary, and other parts of the genitourinary system. Operation must be immediate and radical. Every tumor of the testicle should be treated as malignant until proved otherwise.

In one of the two cases reported the operation was completely successful.

**Primary Tuberculosis of the Genital Organs in Children.**—Dr. O. Lyons, of Denver, states that tuberculous affections of the testicle may occur. The operation of choice is epididymectomy with removal of the vas from the pelvis, obviating complicated convalescence. Tumors of the prostate should not be surgically interfered with. He describes the operative technic and gives lantern slide demonstrations.

**The Pseudodiphtheria Organism in the Urinary Tract.**

Dr. P. W. Townsend, of Rutland, Vt., in this paper reports a case of cystitis with the cystoscopic appearances and subjective symptoms of renal tuberculosis. Bacteriologists have failed to demonstrate the organism in cases of smear of animal inoculation. The pseudodiphtheria bacillus was found in pure culture. The pseudodiphtheria bacillus is considered to be a nonpathogenic organism. A review of the literature reveals only one similar case, which was reported by Dr. Rosenow, of Chicago. The pseudodiphtheria organism is frequently associated with other organisms in chronic urethritis. The author gives a summary of the literature and a report on the bacteriological examination of eighty specimens of apparently normal urine.

**An Experimental Study of the Value of the Internal Use of Hexamethyamine, with the Report of a Simple Clinical Method of Quantitative Estimation of Formaldehyde.**—Dr. Frank Hinman, of Baltimore, relates his experiences in the uses and the results obtained by the use of hexamethyamine internally. He discusses its antiseptic value as regards the urine, and calls attention to the fact that in many cases the amount in the urine is too small for evidences of its presence to appear. It must be present to the extent of 1,300,000 in the urine. He details the qualitative and quantitative tests, and gives tables for estimation. He states the conditions upon which urtoretropin conversion depends. The intervals of administration should not be less than sixty-four hours. The dependability of the results is shown. Clinical and Laboratory Salvarsan Relapses, and their Remedy.—Dr. M. L. Heddingsfeld, of Cincinnati, speaks of untoward results and their prevention. Very careful technic is required in the administration of salvarsan. An error of hundred units would be fatal. The therapy should be controlled by frequent Wassermann tests.

**Progress in the Treatment of Syphilis.**—Dr. Victor Veckl, of San Francisco, critically reviews the later methods in the diagnosis and treatment of syphilis.

**TUESDAY, JUNE 17TH.**

**The Teaching of Pathology and Therapeutics.**—Dr. R. L. Wilber, of San Francisco, concludes his address by pointing out the present unsatisfactory condition in the therapeutic art. Much of this was attributed to the unscientific basis on which therapeutic agents are employed. This has led to therapeutic nihilism and the origin of the drugless cult. He lays stress on the danger of attempting to diagnose and treat conditions, and he lays stress on the importance of keeping the mind still at work after the diagnosis has been made, and of associating therapeutic practices with clinical medicine and surgery; with the says, that sometimes by the practice of bedside pharmacology and therapeutics.

**The Quality of Drugs Sold to Dispensing Physicians.**—Dr. A. F. Puckner, of Chicago, reports no evidence of sophistication found in the drugs sold to physicians by the large drug houses. He shows that the practice of the dispensing physician. They may be a little less reliable in tablets and pills showed a greater variation in weight than those put out by the larger manufacturers, but this was not universal. He concludes that the criticism by pharmacists is unjustified though for the proprietary specialties it is warranted.

**The Solubility of White Leads in Human Gastric Juice and Its Bearing on the Hygiene of the Lead Industires.**—Dr. A. F. Puckner, of Chicago, determines the solubility of lead carbonate and lead sulphate in human gastric juice, obtained from a gastric fistula. He finds the former soluble to the extent of forty-six per cent., while that of the latter is only seven per cent. Experiments showed the carbonate was almost toxic to dogs and cats than the sulphate. The solubility is largely dependent upon the amount of free hydrochloric acid present, as he has found that the ingestion of milk delays the absorption which may be due to the fixation of the hydrochloric acid by the proteid of the milk. Owing to the great difference in the solubility of the two salts, it is pointed out that the carbonate should be eliminated for inside painting where there is danger of lead poisoning.

**WEDNESDAY, JUNE 18TH.**

**Treatment of Anginal Pains.**—Dr. C. L. Greene believes the chief factor in anginal pains is due to strain on a weak and laboring heart, and that the treatment should be directed along the lines of relieving fatigue by having in mind all the factors that produce this condition.

In the way of drug treatment he relies principally upon morphine, since this also tends to quiet the psychic element so frequently associated with the attack.

**Internal Hemorrhages: Can We Control Them?**—Dr. Frank Billings contends that the thing desired in internal hemorrhages is to produce thrombus formation, which is best accomplished by abstinence from food and keeping the patient quiet by morphine. Ergot, ephedrine, and hydromorphone are contraindicated, since they tend to prevent clot formation by raising blood pressure.

**The Value of Diuretics in Cardiac Disease.**—Dr. A. D. Hirschfelder calls attention to the methods employed to produce diuresis in cardiovascular diseases and holds that digitalis is the diuretic of choice through its effect on the circulation, increasing systolic output of the heart and relieving pressure and dilating the small vessels.

**The Value of Diuretics in Acute Experimental Nephritis.**—Dr. H. A. Christian experimenting on rabbits, finds that nephritis induced by uranium nitrate is not reversed by diuretics. The death rate is great. Nephritis is severe, but in moderate cases these drugs are effective in improving the renal function as shown by the phenolsulphonphthalein test.

**Therapeutic Pneumothorax as a Palliative Measure.**—A Report of Two Cases in the Cincinnati Tuberculosis Hospital.—Dr. Kennon Dunham and Dr. Charles S. Rockhill have produced an artificial pneumothorax in tuberculous patients with very encouraging results. Sufficient gas is injected into the pleural cavity on one side to produce collapse of the lung. This measure was found very effective in checking and preventing pulmonary hemorrhage and at the same time the tuberculous cavities become obliterated by the pressure of the gas, as shown by the skiagraph. The treatment is only claimed to be effective in certain favorable cases.
Treatment of Pneumonia by Specific Serums.—Dr. Kutus Cole classifies pneumococci into four different groups, each differing in toxicity. The serum produced by the injection of one group does not operate against the toxins of the other groups. This is one of the explanations offered why antipneumococci serums have not proved successful in the treatment of pneumonia. Stress is laid upon the importance of determining the specific group to which the infecting organism belongs, which may be determined by the agglutination test. All patients have shown a marked reaction where the appropriate serum has been employed.

Antistreptococcus Serum.—Dr. G. H. Weaver emphasizes the importance of using antistreptococcus serum that is active and employing larger doses than has usually been given. No improvement may be expected unless a true streptococcus infection is present.

The Treatment of Lobar Pneumonia with Partially Autolyzed Pneumococci and Pneumococcus Extracts.—Dr. E. C. Roseveor in a series of cases shows that the partially autolyzed or detoxicated pneumococci may cut the disease short if given early, and does reduce mortality. In the last stages it has not proved so efficient, but he believes it is a useful remedy in the treatment of pneumonia.

Nonsurgical Treatment of Cirrhosis of the Liver.—Dr. N. S. Davis reports good results in the treatment of hepatic cirrhosis by keeping the patient at rest, a milk diet, and administering cathartics. Unless this treatment the ascites entirely disappears and by observing a careful diet fairly good health may be enjoyed for years.

Venous Blood Pressure as Influenced by the Drugs Employed in Cardiovascular Therapy.—Dr. J. A. Capps, experimenting on dogs, finds that the drugs, commonly employed in cardiovascular therapy have little, if any, effect on venous pressure. Small doses of ephedrine is ineffective, while large doses produce a rise. A fall is produced by the nitrates and large doses of morphine.

The Elimination of the Digitalis Bodies.—Dr. R. A. Hatcher of animal experimentation finds no evidence that the digitalis bodies are destroyed in the circulation, although they disappear very rapidly.

Thursday, June 19th.

Clinical Observations on the Emergent Action of Digitals.—Dr. Cary Edgerton produces evidence to show that the nausea and vomiting resulting from the administration of digitals is not due to its local irritant action upon the stomach, as commonly supposed, but that it acts directly upon the vomiting centre. In no case should nausea and vomiting be induced by the administration of a single large dose of the drug. This phenomenon only occurs after absorption of the drug, as evidenced by the slowing of the heart and diuresis. Where there is no evidence of digitalis absorption there is no nausea and vomiting.

Radium in Internal Medicine.—Dr. L. G. Rowntree in a review of the literature states that about eighty per cent. of all cases treated in continental Europe show signs of improvement by radium treatment. The methods of administering are by the drinking and inhaling of the watery emanations. His experience in this country, where only a small number of patients have been treated, have not been encouraging, although cases of arthritis deforms show considerable improvement.

Hydrotherapy in Nervous Fatigue.—Dr. C. Pope points out the beneficial results of hydrotherapy in nervous fatigue if carried out in a scientific manner, which is best accomplished in sanatoria, while in the hands of the unskilled it is called quackery. It is emphasized that hydrotherapy is a remedial agent and belongs to medicine and not to charlatans and quacks.

What Can be Done in Cancer with Röntgen Rays.—Dr. A. F. H. Fisher states that cancer without metastasis may be symptomatically cured (i. e. scar tissue only remaining) by the use of the Röntgen rays. Where glandular involvement is present surgical measures should be employed.

The Healing Process of Osteosarcoma.—Dr. G. E. Pfahler is able to demonstrate by the skograph that in the healing process of osteosarcoma treated by the Röntgen rays the deposit of lime salts is one of the chief factors leading to the formation of bone tissue and replacing the tumor mass.

Deutsche Medizinische Wochenschrift.

May 1, 1913.

Theory of Hematoporphyria.—C. Hegler, E. Fraenkel, and O. Schumm report the following résumé of their work: The histological examination of a patient showed that, in various internal organs, great amounts of pigment exist; part containing iron, part no iron. The bone substance was slightly pigmented with iron; the bone marrow contained many erythroblasts of the normoblastic type, which was an expression of active regeneration of red blood cells. The afterproof of iron free cells in connection with the pigment cells pointed to the loss of many red cells. This resulting loss of red blood cells, possibly from earliest youth, should give us the key to the entire process. By it the distribution of pigment in the skin and different organs is explained, as also continuous dark color in urine, darkness of bones, and roots of teeth, and the reddish brown coloring of the skeleton. The examination with the spectroscope has proved that hematoporphyria is a characteristic biproduct of hemoglobin.

Exanthema after the Use of Copaiba Balsam.—W. Fischer, from his personal observations, questions whether he can recommend copaiba balsam preparations or return to the use of santol oil. Even this last is not free from slight untoward action, which results in gastric distress and pain in the region of the kidneys.

May 8, 1913.

A New Diphtheria Prophylactic Remedy.—Von Behring believes that a remedy for diphtheria which, after one or two treatments, would result in protection for an extended period of time, such as is the case with the vaccine lymph of Jenner, and which would leave no ill effect on those vaccinated, would not be a superluous discovery. In the face of advances which we owe to the diphtheria serums in coping with the disease, and in spite of the indisputable fact that we may also secure prophylaxis with the therapeutic serum, statistics show that, for instance, in Berlin the diphtheria mortality increased from 2,997 in 1906 to 11,578 in 1911, and since then appears to have gone still higher. Further, as we know that, for good reasons, the general use of preventive serum injections have discontinued, it can be readily understood with what energy, and that the author is vigorously proceeding to have his remedy proved by other investigators for the purpose of securing more extended observations. Jenner, it is known, had to depend on a large number of statistics for the success of his remedy.

Pernicious Anemia.—Queckenstedt says it would be gratifying if the familiar diminution or absence of hydrochloric acid would permit of being properly substantiated. Large experience in this matter is not at hand, though several single important observations have been made. Of three children who were found to have gastric achylia, one died of pernicious anemia, and in four more showing variations of acidity one other such case was observed. Meagre as are these results, they
help in assuming a constitutional achylia made possible by the anemia. Some importance may perhaps be attached to the fact that not a few of the individuals suffering from pernicious anemia become ill at an early age. What rôle the achyla plays in the genesis of pernicious anemia, and how important a factor it is, is at present only a matter of conjecture.

May 15, 1913.

The Action of Collargol Enemas in Septic Processes.—W. Wolf believes that the good effect of collargol enema has been clearly demonstrated. He purposely waited after each injection until the next rise of temperature, so as to more effectually show the action of the remedy. When there was no question of the favorable effect of the treatment the enemata were given independently of the temperature every fifth day. That the intravenous injection of collargol was ineffectual in a case reported was probably due to the prompt development of a thrombus of the basilic vein, by reason of which a large part of the fluid was not distributed in the circulation. The author was put on his guard by this accident, and refrained from injecting the other arm of the patient. He also states that eight collargol enemata given his patient did not cause the least irritation of the rectal mucous membrane.

May 22, 1913.

Antiluetin.—M. Tsuzuki states that antiluetin promises good results used alone or in combination with the old antisiphilitic remedies. Antiluetin is injected subcutaneously under antiseptic precautions, and the author prefers the intrascapular region. Patients are not hampered in their daily occupation by this method. The treatment is by increasing doses, beginning at 0.025 grammes and increasing to 0.05 grammes. Then smaller doses given for four or five days, until the total amount of from 0.15 gramme to 0.3 gramme is reached. Should patients bear these injections well, the treatment is continued. In the case of less sensitive persons one can give daily doses of from 0.01 grammes to 0.1 gramme of antiluetin.

Case of Rare Disturbance of Potency.—Lissmann relates the case of a married clergyman, desirous, like his wife, of having children, who had suffered from years from lack of ejaculation. On examination of semen, procured by masturbation, the spermatozoa were found to be normal in character. The condition was thought to be possibly due to inactivity of the ejaculatory centre, and two epidural injections of yohimbine were given within an interval of four days of normal saline solution, with from twenty to thirty drops of a two per cent. solution of yohimbin). This stimulated the erections for a time, but otherwise was without effect. Owing to the great desire of the couple for offspring, the author suggested the possibility of ejaculation by means of masturbation up to the moment of ejaculation, when the penis was to be inserted into the vagina. Conception, however, did not result, and finally the patient was advised to resort to artificial impregnation.

May 29, 1913.

The Importance of Analyses of Spinal Fluid and Blood Serums in Neurology.—D. M. Kaplan asserts: 1. Serology is of the greatest importance for the diagnosis and therapeutics of nervous diseases. 2. It is possible to distinguish between syphilitic and nonsyphilitic affections on the one hand, and between dementia paralytica and lues cerebrospinalis, on the other; even when the differential diagnosis is not clear clinically. 3. The cell content of the spinal fluid is to be considered in treating a case of tuberculous specifically or otherwise. 4. The serological picture is one in which most syphilitic affections will be modified by specific treatment. 5. It is capable of exhibiting serologically a characteristic picture for beginning and for fully developed paralysis. The latter is not to be treated specifically. 6. In spinal cord compression one usually finds high protein content and a decrease in cell multiplication.

Two Cases of Eclampsia Resulting Favorably after the Use of Hypophysis Extract.—A. Schlossberger states the use of hypophysis extract in all cases of eclampsia which are to be conservatively treated, so as to determine whether the remedy has antieclamptic properties, in fact, or whether the good result noted in the author's cases was simply a matter of post hoc.

ZEITSCHRIFT FÜR AUGENHEILKUNDE.

May, 1913.

Black Cataract.—A. Elschneg and R. von Zeynek have, they assert with positiveness, determined from the results of chemical analysis that the coloring matter in black cataract is in no way connected with the coloring matter of the blood.

Experimental Studies of Fluorescence of the Human Lens.—J. von Sepibus gives the results of a large number of experiments with uvial glass and states that he obtained a yellow green fluorescence of the human lens which is more marked as age increases. The color of this tends in youth more toward green; in age toward yellow. No fluorescence worth mentioning was obtained from the swollen masses of lens substance in traumatic cataract, and no distinctly visible fluorescence could be seen in remains of the lens capsule or in exudates in the pupil. The aphakic pupil was not fluorescent.

LYON MÉDICAL.

May 25, 1913.

Pathology of Disseminated Sclerosis.—L. Bériel states that from the standpoints of etiology, symptomatology, and course, disseminated sclerosis (sclerosis en plaques) can only with difficulty be conceived of as a definite, single disease. The unity of the disorder now depends chiefly upon its pathological substratum. For the production of the sclerotic plagues there is required merely a diffuse, subacute, nodengenerative myelitis or myeloencephalitis, upon which are grafted localized vascular changes. These conditions having been supplied, the lesions are readily accounted for according to the general laws of the nutrition and evolution of tissues. The original myelitis does not depend upon a single, specific cause.

PARIS MÉDICAL.

May 24, 1913.

Urinary Pepsin and Nephritis.—M. Chiray and R. L. G. Clarac state that, of all the methods of estimating the urinary pepsin hitherto employed,
that in which edestin is employed as the albumin to be digested is the best, though even this procedure is not altogether satisfactory. The gastric mucous membrane produces proppepsin, of which a portion is not converted to active pepsin, passes into the blood, and is eliminated by the kidneys; becoming in part activated to pepsin when in contact with the renal epithelium. The urine contains both pepsin and proppepsin, and the latter is activated by the acid present in the edestin solution used in the test. Whereas in but one of nine patients suffering from various affections—cirrhosis, pleurisy, rheumatism, cancer—was the urinary pepsin found above normal by the authors, it was above normal in five of six cases of chronic nephritis. Urine treated with toluene and placed in the incubator was found to be the seat of a pronounced autodigestion, causing a progressive diminution of its albumin content.

**Palpation of the Liver in the Standing Position.**
—L. Plantier asserts that, in view of the frequency with which unsuspected abnormalities of the gall-bladder are found at autopsy and upon laparotomy, there is evidently something wrong with present methods of physical examination of this organ. He has found, indeed, on many occasions, that where no sign of gallbladder trouble can be elicited upon examination of the patient in the recumbent posture, characteristic gallbladder tenderness is noted upon deep pressure at the appropriate point when the patient assumes the standing position. Apparently the gallbladder recedes above the costal margin during recumbency, and is thus not accessible to examination.

**PRESSE MÉDICALE**

**Diagnosis of Aortic Insufficiency with the Sphygmomanometer.**—Camille Lian, in thirty-six cases of aortic insufficiency, found the maximal pressure higher than normal in twenty-two instances, normal in eleven, and slightly subnormal in three. The minimal pressure was normal in twenty cases, subnormal in fifteen, and slightly above normal in one. The most valuable diagnostic information is afforded, however, by the relationship of the two pressures. In sixteen cases the maximal pressure was above normal and the minimal pressure normal; in seven, the maximal was normal and the minimal subnormal, and in five, the maximal was above normal and the minimal subnormal. The characteristic features in aortic insufficiency are thus an increase in the pulse pressure and usually a normal or subnormal diastolic pressure. These features are preserved even where there coexists another valvular lesion, arteriosclerosis, or chronic nephritis. In the average case of aortic insufficiency sphygmomanometry is only an additional confirmatory factor in diagnosis; but in cases where the murmur is but slightly marked or absent (including cases in which there is muscular weakening), where tachycardia renders precise auscultation difficult, and where other valvular lesions are present, the procedure is likely to be of great service. In one half the cases of Hodgson's disease (aortic insufficiency of syphilis and arteriosclerotics), viz., those in which there is well characterized chronic arteritis and interstitial nephritis, the maximal pressure is very high and the minimal normal or almost above normal; but in the remainder the typical pressure conditions are the same as in Corrigan's disease (aortic insufficiency of rheumatic origin).

**REVUE DE CHIRURGIE.**
*May, 1913.*

**Technic of Jejunostomy and Its Untoward Sequelæ.**—L. Bérard and H. Alamartine report a case of death following jejunostomy by the Witzel-Eiselsberg technic. All necessary precautions had been taken during the operation, and the fatal ending, due to intestinal obstruction four days after, must be ascribed to the procedure itself. At autopsy the jejunum was found kinked at an acute angle at the point operated on. Two similar fatal cases reported by other surgeons are referred to. The authors consider this form of jejunostomy too dangerous a procedure and too time consuming, and much prefer to it the older "omega" technic advised by Albert and Mayo Robson. This operation they perform under novocaine-epinephrine local anesthesia. The laterolateral anastomosis between the two halves of the loop of jejunum brought to the surface is effected with a Jaboulay-Lumière button; at least ten minutes’ advantage being thus gained over the ordinary suture method. With this procedure perfect continuity is secured and accidents from occlusion of the gut cannot occur.

**REVUE MÉDICALE DE LA SUISSE ROMANDE.**
*May, 1913.*

**Banti’s Disease in Infancy.**—A. D’Espine reports two cases in which the anemia and splenomegaly characteristic of Banti’s disease were noted, respectively, at the ages of seven and fifteen and a half months. In neither case was syphilis a factor. The author is led to emphasize the early onset of Banti’s disease. Splenomegaly may often have passed unnoticed until adult life and the disease actually had started in infancy. Some cases of rachitic splenomegaly, considered as arising from syphilis by certain authors, are actually incomplete (frustes) cases of Banti’s disease. Spontaneous recovery from Banti’s disease may occur in children, as in two cases to which D’Espine refers. That the injection of splenic tissue from one of the author’s cases into a monkey gave negative results would appear to show that the disease is not due to infection.

**New Uterine Curette.**—Jambé describes an instrument consisting of an ordinary sharp curette blade borne by a metallic ring, which is slipped over one or two fingers in such manner that the tips of the latter project. The chief advantages of the device are that direct control of the curettine by the fingers is afforded and that the leverage of the long handle of an ordinary curette, with the attendant danger of undue injury to the deeply seated uterine cavity, is avoided. The smaller monodigital device is to be used where dilatation is insufficient to admit two fingers, in cases of abortion or premature labor, while the larger bidigital instrument intended for post partum curettage in cases where complete evacuation cannot be secured with the hand alone.
Chloride Free Treatment of Epilepsy.—V. Demole reports the results obtained in four epileptics by the use of Ulrich's sedobrol, a mixture of potassium bromide with a minimal quantity of sodium chloride and with fats of extracts of vegetable albumins, intended to afford the advantages of “chloride free” treatment without the disadvantage of anorexia and dyspeptic disturbances arising because of distaste for unsalted food. The sedobrol tablets are dissolved in chloride free soup, to which they impart an attractive flavor. The efficacy of the remedy was shown in each of the patients receiving it, the number of seizures diminishing, on the average, by twenty-nine per cent. from what they had been during bromide treatment alone, and becoming more frequent again when the preparation was discontinued. No dyspeptic trouble was experienced during its use. The remedy was also employed with success in a case of hysteroepilepsy, both the body weight and mental condition showing distinct improvement under its influence.

BRITISH MEDICAL JOURNAL.

On Avoidable Difficulties in the Hand Feeding of Infants.—Eustace Smith ascribes much of the trouble to the careless handling of the infant at the time of birth and shortly thereafter. At birth the infant passes from a temperature of about 100° F. into one of from 65° to 70° F., and carelessness in bathing and attending to it subjects it to prolonged chilling, which gives rise to considerable shock and disorders the digestive powers. Such children vomit even the mother’s milk, and are then put upon formulas. On the bottle they suffer even more than at the breast, and the food is blamed. The real trouble, however, is a catarrh of the stomach. The continued exposures for each day’s care serve to keep the condition aggravated. For the avoidance of much trouble in artificial feeding the first rule given by Smith is, “Take care that the infant is bathed as quickly as possible in hot water, and that his feet and legs are never allowed to get cold.” The second rule is directed to the maintenance of proper digestive powers and their encouragement by variety of flavor in the food. Smith believes that this is of great importance in hand fed infants, and especially to those whose digestive difficulties have already been a cause of anxiety. It will usually be sufficient to give two differently tasting foods alternately during the day, and a third for the night. In exceptional cases a greater variety may be needed.

Autogenous Vaccines in the Treatment of Chronic Joint Affections.—Basil Hughes considers the so called rheumatoid arthritis as a metastatic arthritis due to some primary focus of infection. Such foci have been most frequently found, in his cases, to lie in the mouth about the teeth, in the nose and nasopharynx, in the ear as a chronic otosclerotic, in the lungs as bronchitis or bronchiectasis, in the intestinal tract associated with dyspepsia and intestinal stasis, and, lastly, in the female pelvic organs as leucorrhoea of septic origin, usually due to Bacillus coli. In all such conditions the offending organism or organisms should be isolated from the primary focus (it is usually impossible to cultivate them from the joints), and an autogenous vaccine should be given for one or two doses. This raises the phagocytic powers of the patient and it is then time to give the infected region the needed local treatment. The use of the vaccine is to be persisted in for long periods of time if one is to succeed in the treatment. Hughes believes that chronic gonorrheal arthritis is due to a mixed infection with the gonococcus and the staphylococcus, both of which can be cultivated from the interior of the urethra. A vaccine containing from 100 million gonococci and 150 million staphylococci up to 500 million of the former, and 1,000 million of the latter, is to be used, and after the second dose the chronic gleet is to be treated locally. Excellent results follow this method, but it often requires many weeks or months for a cure.

Vaccines in the Treatment of Chronic Bronchitis and of Asthma.—J. H. Harvey Pirie has treated some sixteen cases of the former condition with autogenous vaccines made from the sputum, and containing all of the probably pathogenic organisms present. The most commonly found organisms are the pneumococcus, Micrococcus catarrhalis group, streptococci, and staphylococci. Attention is called to the necessity for the inclusion in the vaccine of colonies of each of the several strains of the Micrococcus catarrhalis group which are usually found, as many of the strains are nonpathogenic, and the selection of the one which is offending is impossible bacteriologically. Seven of his sixteen patients are almost cured, four show marked improvement, four slight improvement, and one no improvement. In asthma the same varieties of organisms were found as in bronchitis, but in the former the pneumococcus was found in every case, while in the bronchitis cases two of the sixteen showed no pneumococci. Of nine patients with asthma, two have been practically cured, five considerably improved, one shows slight improvement, and one, none.

LANCET.
June 11, 1913.

The Place of Climatology in Medicine.—William Gordon discusses the general factors which go to make up a climate, and outlines their influence on healthy humans. As to their effects upon disease, he recalls that he has shown that exposure to prevalent rain bearing winds is a marked factor in both the occurrence and the prognosis of pulmonary tuberculosis. In pneumonia, a small series of observations would seem to indicate that great altitudes, and particularly cold dry winds, exert a considerable influence leading to the greater frequency and intensity of the disease. On the other hand, in bronchitis damp wind seems to increase its prevalence. Knowledge of the influence of such factors, and of the nature of the factors of climate which characterize given sections of the country, gives us an important element in diagnosis and in prognosis, for if a patient is known to come from a region in which pneumonia is prevalent and severe, we are justified in anticipating a doubtful outcome. The influence of climate does not seem to be confined to the infectious diseases, for it has been found by analysis of the frequency of cancer and of the age of its incidence, and that at which it kills.
that in certain rural districts the disease is relatively rare, occurs later in life, and death results from it at a much more advanced age, than is the case in towns or in the country in general.

The Finsen Light Treatment at the London Hospital, 1900-1913.—J. H. Sequeira reports that of a total of 1,039 patients treated efficiently for lupus during the past thirteen years, 544 have remained cured for from three to thirteen years; 186 have remained cured for less than three years; 117 have been essentially cured, requiring, however, occasional treatment for slight recurrences; 161 patients have improved; and thirty-one have been wholly uninfluenced by the treatment. Not all of the benefits recorded are ascribable solely to the light treatment, for some cases were also helped out by a few exposures to X rays, and some were treated surgically, in addition to the use of the light.

Breast Feeding.—David Forsyth had an infant carefully weighed before and after each nursing for a period of seven weeks, beginning on the fourth day after birth. The results show that there is a general increase in the average daily consumption of milk from week to week, but that this is neither uniform nor uninterrupted. Further, the daily amounts taken vary within wide limits, and the amount taken at a single feed is even more variable. In the second week so large a single feed as 125 c. c. was taken on two occasions. The average feeds ran: Twenty-eight c. c. for the first week; fifty-seven c. c. for the second; forty-six c. c. for each of the next two weeks; sixty-six c. c. and sixty-five c. c. respectively for the fifth and sixth weeks; and seventy-seven c. c. for the seventh week. From the finding of enormous variations in the sizes of individual feeds one is forced to believe that the "test feed" method of estimating the needs of a child is worthless. Another notable feature of the observations was that the variable consumption of the milk did not seem to run in cycles, but was quite irregular. Forsyth believes the variation due in large measure to maternal factors, rather than to differences in the infant's appetite. No food or drug reputed to have galactogogue powers had any influence on the flow of milk in the case thus carefully studied.

Breast Feeding.—Disney H. D. Cran advocates the teachings of Varriot to "let the child on the breast drink according to its appetite." From a large series of cases, all of which were conducted along this plan, it was found that the infant mortality did not exceed 4.5 per cent., being only 3.14 per cent. in 1912. The amount of milk thus taken by the child may vary from one sixth to one twelfth of its body weight in twenty-four hours, and is never so low as one tenth, as is generally taught. If the child has taken a little too much milk there is simple regurgitation. The restricted feeding advocated by many almost always leads to undernutrition, with crying, vomiting, diarrhea, wasting, etc. The use of scales more often than once a week in the case of a young mother who is healthy is to be deprecated, for it often leads to worry if the child happens to take but a small feed at the meal chosen as the test one. The methodic use of the scale is indicated when a child on the breast ceases to increase in weight, and this will usually show that the secretion of milk is deficient.

A Case Having a Bearing on the Localization of the Auditory Centre.—William Boyd and J. S. Hopwood report the post mortem finding of a case of complete destruction of the entire left temporal lobe except the third convolution, and the anterior extremities of the second and first convolutions, the last of which bears on its upper surface the anterior gyrus of Heschl. In this latter the auditory centre has been thought by some to lie, and the present case seems to lend confirmation to this view, for the patient showed no deafness during life.

An Experimental Research into the Origin of the Inorganic Chloride in the Gastric Secretion. —Charles Singer obtained gastric juice from fasting cats by means of a stomach tube and pilocarpine. Seven different samples were tested for the inorganic chloride, and it was found to be present in all. He therefore concludes that the inorganic chloride in gastric juice is in large part due to secretive or osmotic processes in the stomach wall, and not to introduction in the food, and that it must, therefore, be affected by pathological changes in the wall. Hence the amount of inorganic chloride becomes of pathological and clinical significance.

**JOURNAL OF TROPICAL MEDICINE AND HYGIENE**

**May 1, 1913.**

Treatment of Suppression of Urine in Blackwater Fever.—H. S. Stannus reports a case in which, after hemoglobinuria had been present twenty hours and complete suppression forty-eight hours, nephrotomy (unilateral) was performed. This resulted in the passage of small amounts of urine, beginning within twenty-four hours after the operation and continuing until death took place in the presence of uremic symptoms, on the evening of the fifth day after operation. Although the procedure was unsuccessful in saving life in this case, the author thinks it possible that intervention at an earlier period in the suppression would succeed in cases of this kind. The first desideratum is to ascertain how long suppression can exist before a spontaneous return of renal function is precluded in a large proportion of cases.

Spider's Web and Malaria.—Frederick Knab, referring to the view recently urged that the web making spiders are effective destroyers of malaria transmitting mosquitoes, points out that while it has been generally taken for granted that mosquitoes are actually entangled in the webs, just as are other diptera, records based upon first hand observation of such occurrence are exceedingly few. On the other hand, the author has observed mosquitoes to choose spider webs as a resting place and habitually to repose there, without in the least becoming adherent to their meshes. In every case the mosquitoes so observed were anophèles, and furthermore, in the vicinity of Washington, D. C., the author found that all the anophèles on the webs belonged to the species Anopheles quadrinaculatus, although a second species, Anopheles punctipennis, was present in the locality in large number. The latter species carefully avoided the webs. Since
Anopheles quadrimaculatus is the principal malarial transmitter in the northern United States, while the more abundant Anopheles punctipes has been proved incapable of serving as the host of the malarial parasites, it would appear that in some cases at least, the spider webs have no effect in checking malaria. The author could not find a single record of anopheles caught in a web.

May 15, 1913.

A Clinical Study of Malarial Fever.—J. P. Bates, from a study of malaria begun in Panama in 1905, and covering a large number of cases, concludes that this affection is not analogous to other infectious diseases in that the greater the infection the more prolonged the course, but either responds to quinine within three to four days—in a few instances of primary infection and in children, within six days—or rapidly terminates in a fatal issue. Systematic examination of the stools, Widal tests, blood cultures and a careful study of symptoms, have convinced the author that the idea long prevalent that malaria is in some instances only slowly influenced by quinine is incorrect, and that the cause of this mistake has been confusion of three conditions, viz.—uncinaria amnesia, kala azar, and mild typhoid fever, with malaria, owing to the great clinical similarity. True malaria is a very simple entity and is not difficult to cure if treatment is begun before the organism is overwhelmed by the infection. Mild typhoid fever, as proved by cultivation of the bacilli from the blood, has given rise to much confusion, because its temperature curve is often irregular, as in the so-called "remitting" or "subcontiguous" type of malaria, and because some typhoids of moderate severity terminate abruptly, as malarial fevers often do. At least, some of these cases have malarial parasites in the blood, along with the typhoid infection. In differentiating mild typhoids from malaria, the blood cultures must be made within from twenty-four to thirty-six hours after admission.

BOSTON MEDICAL AND SURGICAL JOURNAL.
June 10, 1913.

Concerning Diabetes Insipidus and the Polyurias of Hypophysal Origin.—Harvey Cushing summarizes the experimental data by saying that: 1. The infundibular region contains, in addition to the substance capable of glycogenolysis, a chemical body or hormone capable of eliciting diuresis. 2. Under certain operative conditions which entail posterior lobe manipulations there often occurs a diuretic response, and occasionally an extreme polyuria, whereas a temporary diminution in the excreted urine is apt to follow other operative procedures requiring an equally long anesthetization. 3. Posterior lobe implants may cause a temporary polyuria, which subsides on the removal of the implanted tissue. 4. Stimulation of the autonomic system of nerves to the gland elicits diuresis. 5. Certain operative procedures, such as separation of the infundibular stalk, and occasionally a simple posterior lobe excision, may call forth a somewhat prolonged polyuria. In connection with clinical observations he suggests not only that the emotional polyurias are in all likelihood the expression of a neuronic discharge of hypophysal secretion, but also that the clinical polyurias of longer duration are in many instances merely the symptomatic expression of an internal secretory disturbance brought about by injury or disease involving the hypophysal neighborhood. Hence, whether or not there actually proves to be a form of polyuria of primary renal origin, our present conceptions of so-called diabetes insipidus need to be recast, with special reference to the factor of the secretory activity of the pituitary body, and particularly of its posterior lobe.

Diagnosis and Treatment of Diphtheria.—Joseph B. Greene makes the following points: 1. The diagnosis of diphtheria depends primarily on finding the organism. Cultures should be taken of every sore throat in children, and of suspicious nasal discharges. But in the absence of a positive finding, if the symptoms point to diphtheria, antitoxin should be given, especially if the symptoms are severe. 2. Much larger doses of antitoxin should be given than those suggested in the textbooks. 3. Laryngeal cases are serious, partly from mechanical obstruction, requiring prompt relief from the stenosis, and large doses of antitoxin. Intubation is preferable, in the main, to tracheotomy. Laryngologists should perfect their technic in this operation until it becomes a fairly simple one. 4. Epidemics of diphtheria are kept up largely by “carriers.” They should be sought out, isolated, and the abnormality treated. Diseased tonsils and adenoids may require removal.

Tuberculosis of the Epididymis: Its Effect upon Testicle and Prostate.—J. Dellinginer Barney says that the epididymis is the primary focus in the vast majority of cases of genital tuberculosis. The disease is bilateral in 41.6 per cent. of all cases, and becomes so within six months of the involvement of the first side in thirty per cent. The prostate and vesicles are infected in seventy-five per cent.; this infection taking place in the first six months in thirty per cent., and in the first year in fifty-four per cent. The infection takes place quite as often in the presence of unilateral as of bilateral epididymitis. The urine is pathological in forty-three per cent. of all cases; bladder irritability is found in thirty-five per cent., and in about half of these it occurs in the first six months. Tuberculosis, past or present, of organs other than those of the genitourinary tract, is to be expected in thirty-three per cent. Clinical observation shows tuberculosis of the testicle in forty-four per cent., but the pathologist finds it in sixty-six per cent., and of these the infection takes place in the first six months in fifty-three per cent. As the infection may become widespread in the first six months, removal of the epididymis is indicated at the earliest possible date. It is rarely necessary to remove the testicle, as it was not required in sixty-seven epididymectomies.

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.
June 21, 1913.

The Treatment of Narcotic Addiction.—Alexander Lambert describes a treatment for alcohol, morphine, and other drug habits, the essentials of which cannot be altered. The treatment consists of the persistent administration of a belladonna mixture, in small doses, and thorough elimination by a
mercurial cathartic, as blue mass or calomel, given in the form of compound cathartic pill or alone. Some patients who are easily salivated by calomel can take blue mass. The chologogue action is essential. Mere catharses is insufficient in the process of elimination, as are also colonic enemas. There must be the chologogue action from above. This treatment is not offered as a cure of morphinism or as a cure of delirium tremens or chronic alcoholism, but it will remove the terrible craving accompanying these addictions. When, unaided, the patients endeavor to give up the drugs or are made to undergo the slow withdrawal without some soothing substitute. It is superior to the old methods of slow or rapid withdrawal. Deprivation of a drug is not equivalent to the elimination of that drug from the system. Suffering follows deprivation, relief follows elimination. This treatment, and no other known treatment, can prevent patients, after being freed from such addiction, from re-poisoning themselves by resuming the use of the drug, which has previously poisoned them and led to their habitual intoxication. Though each individual presents a separate problem, this treatment is suggested as the best means of "unpoisoning" the patient and placing him in a position where he can be approached with a clear, unpoisoned mind, and protected from self destruction.

Animal Experiments with von Ruck's New Tuberculoproteins.—From a series of experiments made with this vaccine upon guineapigs, R. S. Cummings concludes that immunity was not produced by the vaccine, but it would seem possible that as the vaccinated animals became sick first, they were more susceptible at the time of inoculation than the controls.

Accidents Following the Subdural Injection of Antimeningitis Serum.—Simon Flexner admonishes us not to lose sight of the fact that in epidemic meningitis we are dealing with a highly fatal malady, and the one means now possessed to combat it is the antimeningitis serum. It is not justifiable, therefore, to withhold the remedy, in spite of some small risk, in view of the far greater dangers from the disease itself. Nor should we always ascribe serious symptoms to the serum, even when they follow closely on the treatment. Sudden death not infrequently occurs in epidemic meningitis; cases have been reported in which death has taken place while the serum injection was being prepared, and even before lumbar puncture had been done. The antimeningitis serum should not be discredited because of an unfortunate experience. When everything is considered, such action seems hardly defensible.

Advanced Treatment of Puerperal Infection.—The rational treatment of puerperal infection, according to Robert T. Gillmore, demands that we ascertain by a blood culture the germ causing the infection. To this end a tight bandage is applied to the upper arm, and the distended median basilic vein punctured with a large needle, under strict aseptic technic, after which about half an ounce of blood is withdrawn into a sterile glass container. From this an antogenous bacterin is made. It requires five days to be absolutely certain that no other living germ is present; it is wise, therefore, after the microorganism has been isolated, to initiate a bacterin treatment with fifteen c. c. of serum intravenously, to be followed with a reliable stock vaccine. The nonoperative treatment of an uncomplicated case of puerperal infection demands complete physical and mental rest, good ventilation, and sunshine, and that drainage be favored by the Fowler position. Cold sponging and an ice bag on the head should be used to control hyperpyrexia. If there is local pelvic inflammation an ice bag is placed over the affected area. Elimination by the bowels and the kidneys should be favored, and normal saline solution, introduced by the drop method into the rectum, will save the stomach, allay thirst, and favor renal elimination. Since this preparation of an autogenous vaccine requires about five days, a serum or antitoxine should first be administered, to be followed by a reliable stock vaccine if the blood count is favorable, and there is an indication that the patient lacks sufficient reaction to combat the disease. The stomach should be carefully guarded, and all useless medication avoided. Reserve the stomach for nourishment only. Feeding should be done with care and at regular intervals. Dispense with breast nursing, unless the mental effect is too depressing. The operative treatment should be limited to cases with absolute indication. The use of antiseptic vaginal and uterine douches is deprecated.

Conservative Treatment of Some Aural and Nasal Conditions by Hot Air and Iodoform.—Edward J. Brown presents a simple and practical method of treating some aural and nasal conditions. Sore throat and earache from acute pharyngitis have been relieved by a single application of hot air and nascent iodine, with no return of the trouble on the following day. This result seems to be due specifically to the destruction of the less resistant bacteria and the drying and shrinking of the tissues with the secondary increase of cellular activity and removal of inflammatory products which interfere with drainage.

The Serum Diagnosis of Pregnancy.—Charles C. W. Judd, in considering the Alberdhalden serum tests, remarks that if putrefactive changes can be excluded, a positive reaction indicates that the tissue was digested by an enzyme of the patient's serum, which, so far as investigations have been able to determine, is present only in the gravid state, the puerperium, and in cases of retained membranes. A negative reaction, however, is strong, if not conclusive, proof that placental tissue is not or has not recently been present in the patient's body. Some thirty or more cases under the care of the writer, and tested by this method, have shown the strict specificity of this test when putrefactive changes, fresh serum, and the proper selection of dialyzers have been carefully controlled.

MEDICAL RECORD.
June 21, 1913.

Incompetency of the Ileocecal Valve.—John H. Kellogg describes the disorders arising from this condition and their treatment. In complete incompetency of the ileocecal valve the passage of a large amount of undigested food from the small intestine into the colon may cause indigestion and diarrhea. When the contents of the small intestine
pass rapidly into the colon, instead of being introduced in small successive quantities, the colon becomes overdistended, stasis occurs, putrefactive processes are encouraged, colitis, pericolicis, or appendicitis may result, and conditions are produced which favor the development of tuberculosis and cancer; pathologic conditions which occur with special frequency in this part of the canal. The drag of this accumulated material upon the root of the mesentery produces obstruction at the junction of the duodenum and jejunum, and so causes duodenal and gastric stasis, the natural consequence of which in these parts, as in every other part of the alimentary canal, is the abnormal development of bacteria and toxines, with infection of the mucous membrane and resulting gastritis, duodenitis, gastric and duodenal ulcer, cholecystis, cholangitis, gallstones, pancreatitis, adhesions about the pylorus, and the duodenum with chronic pain in the pyloric region, and various other morbid conditions connected with the stomach and digestion. Appendicitis and the various troubles referable to adhesions about the ileocecal region are a natural, almost necessary, consequence and incompetency of the ileocecal valve. Ileocecal valvular incompetency interferes with the movement of gases even more than of liquid material, and the bowel is practically unable to deal with gaseous material. Constipation and intestinal intoxication of the highest degree is produced by incompetency of the ileocecal valve. The palliative treatment of the condition includes increased activity of the bowels (three movements daily) and a change of the intestinal flora (by the use of acid forming ferments—Bacillus bulgaricus, Bacillus bifidus). The radical cure, seldom needed in the writer’s opinion, consists in reconstructing the damaged labenum and reproducing the intussusception of the small intestine.

A Clinical Study of the Application of Improved Intravesical Operative Methods in Diagnosis and Therapy.—Leo Buerger reports eight interesting cases demonstrating the useful endovesical operation procedures that can be carried out through the modern cystoscope by means of special instruments. These include the excision of suspected pathologic lesions, the crushing and removal of calculi, the removal of foreign bodies, the snaring of papillomas, the dilatation of ureters, the excision of ulcers for diagnosis and therapy, the exploratory or therapeutic incision of cysts, the synchronous catheterization of three ureters and the synchronous employment of three or more catheters, and the excision of portions of a ureteral orifice for the diagnosis of renal tuberculosis. The technic of operative cystoscopy is minutely described by the writer.

Local Autogenous Temperature Variations, a Cause of Labyrinthine Vertigo.—Edmund P. Fowler states that sufficient heat or cold applied near the static labyrinth will produce vertigo and usually nystagmus in definite directions, depending upon the position of the head. The degree of vertigo, nystagmus, etc., varies with the sensitiveness of the organ and the amount and kind of tissue between the labyrinth and the place where the heat or cold is applied. The semicircular canals and utricle are protected from extreme temperature variations by the poor heat conductivity of the tissues surrounding the labyrinth, and of the blood and tissue currents, and with the usual methods of applying heat or cold, the temperature reaching the canals can be but slightly different from that already surrounding them. The bony walls are only relatively good conductors of heat and their specific heat low, but, being surrounded by poorly conducting bone and tissues of high specific heat, they are quickly affected by temperature changes, and such variations will persist near the area of application for appreciable periods of time. Portions of the static labyrinth are near the surface, and localized inflammations or congestions or anemias may cause variations in temperature which will affect the flow of the endolymph, and, if sufficiently intense, will cause vertigo and other similarly produced phenomena.

**Journal of Nervous and Mental Disease.**

March, 1913.

A Case of Hypoglossal Nuclei Paralysis.—A. M. Moll reports a case which seems to support the theory that the hypoglossal nuclei contain cells which at least partially enervate the orbicularis oris through the seventh pair. The case was apparently one of bulbar thrombosis manifesting difficulty in eating and swallowing with almost complete paralysis of the tongue. There was no involvement of the distribution of the facial nerves except the muscles about the mouth, which were weak and gave electrical reactions of degeneration. There was also weakness in the legs, with increased reflexes, showing involvement of the motor tracts. Improvement gradually took place in all of the symptoms. In the absence of histological studies the case is, of course, not conclusive, but indicates the possibility that some of the facial fibers may arise in the hypoglossal nuclei.

Occurrence of the Syphilitic Organism in the Brain in Paresis.—J. W. Moore has been successful in establishing another link in the chain of evidence connecting paresis and syphilis. In post mortem examinations of the brains of seventy patients with paresis for the organism of syphilis the treponema was found in twelve specimens. Difficulties in the technic indicate that the organism is present in a much larger proportion of the cases. Whether it is present in all, in other words, whether paresis is invariably syphilitic, has therefore still to be proved. The most of the organisms found in these brains were in the cellular layers of the cerebral cortex of the frontal lobe and gyri recti. None were seen in the superficial neuroglia layer nor the pia, as is the case in cerebrospinal syphilis.

April, 1913.

The Present Status of the Knowledge of Apraxia; with the Study of a Case.—Alfred Glascock, in a continued article (March and April) considers the evolution, as well as the present status, of the agnosias and apraxias, and their relation to the aphasis st. To Liepmann is given the credit of having clarified the subject, and it is his classification that the author has mainly adopted. By the term agnosia is understood a mental inability to recognize objects by the aid of the senses when
sensation itself is intact. This may be referred to any of the sensory organs, and constitutes tactile, visual, or auditory agnosia; it includes, or is closely allied to, word blindness, word deafness, and astereognosis. Apraxia, on the other hand is a motor condition or defect of the performance of voluntary movements in the absence or independent of motor weakness. This not only includes the inability to write, but also the inability to handle objects and perform movements which previously required but little effort. The symptoms of agnosia and apraxia are frequently associated in the same case, and, as in disturbances of the use of language, the left cerebral hemisphere in righthanded individuals is principally concerned in their development. An interesting and vital point in the theory of leftsided apraxia is the fact that it may be caused by a lesion of the corpus callosum, or even in the left hemisphere, thus indicating that the extremities of the left side, in association with the right cerebrum, is ultimately controlled by centres in the left cerebrum via the corpus callosum. Precise localization of the different centres concerned in these functions is as yet a matter sub judice, and for its consideration the reader is referred to the original article. The case reported is a careful and detailed study of the clinical manifestations in a patient presenting symptoms of agnosia and apraxia.

May, 1913.

The Aborted Forms and Preparalytic Stage of Acute Poliomyelitis as Observed in the Buffalo Epidemic.—Edward Aislick Sharp, in analyzing the epidemic of poliomyelitis which occurred in Buffalo during the summer of 1912, has collected twenty-nine cases, from a total of 310, which were either aborted forms or cases studied during the preparalytic stage of the disease. The classification is based on symptomatology, into abortive, meningeval, ataxic, and paralytic types. Almost constant symptoms in the preparalytic stage were fever, drowsiness, stiffness of the neck, and constipation, headache, irritability, and twitchings were also generally present. The findings in the cerebrospinal fluid were fairly constant lymphocytes and increased globulin reaction; conditions not sufficient in themselves to differentiate the condition from tuberculous meningitis or the meningeval irritation of acute infectious diseases of different origin.

Mirror Writing and Other Associated Movements Occurring without Palsy.—Charles W. Burr and C. B. Crow describe the case of a man of twenty-six years who was congenitally unable to individualize the movements of his two hands; except for very simple movements the two hands moved symmetrically, with the result that when he wrote with a pencil in each hand, the left produced "mirror writing." In the absence of any evidence of a lesion, the hypothetical explanation is advanced that there was a congenital lack of development of certain association pathways or centres in the brain.

Cerebellar Tumor Gliona: Operation: Recovery.—Max Mailhouse and William F. Verdi present the report of a remarkable case of cerebellar tumor occurring in a girl of fifteen years, and its removal by two stage operation. Location was difficult on account of the bilateral invasion. In spite of the size of the tumor (weight, 107 grammes; dimensions, 7.5 x 6.8 x 4.7 cm.) it was successfully removed one year after a primary decompression, and eight months later the patient had to a large extent regained motor coordinations.

Experimental Studies on the Nervous Mechanism in the Production of Hyperplasia.—Walter Timme reports some experimental operations upon cats in which the pneumogastric nerves were ligated in the thorax below the esophageal plexus. Of nine animals operated on, five lived; they also gained in weight, but were sluggish. They were killed at from 111 to 140 days after operation, and five or six hours after a full meal, and control animals were killed under similar conditions. In the control animals digestion was well advanced, while the stomach contents in the experimental animals were but slightly digested and almost dry. On the other hand, the capacity of the stomach was greater, and the stomach wall much thicker, in each of the experimental animals than in the controls. In particular, the mucosa was thrown into heavy folds, and a microscopical examination revealed an abnormal number of gastric glands, as compared with the controls. The hypothesis is advanced that nervous impulses are dependent upon electric circuits through the nerves, and that ligation of the vagi diminished the currents through them, at the same time tending to increase those to the stomach via the sympathetics. The result of this condition might be to stimulate the trophic influences, and to inhibit the functional activity (secretion and motility) of the stomach.

Letters to the Editor.

THERMOSTABLE TOXINES IN URETHRAL AND BLADDER INFECTIONS.

To the Editor:

In the June 21, 1913, issue of the New York Medical Journal, in an article entitled "Use of Thermostable Toxines in Urethral and Bladder Infections," Dr. Frank S. Crockett states that the bactericidal activity of the blood "is accomplished by a new process, a short cut." Further on he states: "The first use of my toxines were carried out, etc." In the spring of 1912, I. M. Morgan, D.V.S., made a series of autotherapeutic tests on many animals by heating the exudate of disease, filtering it through some coarse material, such as several thicknesses of cheesecloth or gauze, to remove heavier particles, and then injecting the filtrate hypodermically. He published his results in the American Veterinary Review, July, 1912, under the title: "Autotherapy." This article was republished in the London Veterinary Journal for October, 1912, and was referred to by me in my article on "Autotherapy" in the December 21, 1912, issue of your Journal. There I stated: "The writer is making many tests of treating rhinorrhea and kindred diseases by using the patient's own morning urine, he believes successfully." Since then I have received reports from physicians who had filtered the discharge of disease with filter paper, and injected the filtrate. One of these reported had abscess formation.

I would respectfully refer Doctor Crockett to the Croonian Lectures on "The Pathology of Immunity," by Dr. Leonard Dudgeon (Lancet, June 15, 22, 29; July 6, 1912). Doctor Dudgeon made many tests upon animals by centrifugation and pipeting the top fluid before injection. He did not assert that it was a "new process." Assuming that it is a "new process," is it a "short cut" or...
simpler to centrifugalize, heat, and filter, than just to filter through porcelain?

This is neither a "new process" nor a "short cut." Continuing, Doctor Crockett says: "The first use of my toxins was carried out, etc." This is not the "first use of these toxins, nor are the toxins his. Doctor Crockett appears to be alive to the very grave danger attending the injection of living pathogenic microorganisms into the tissues for he says: "The injection of the products of the disease of the infected organism might be carried through the blood stream with the resultant localization of the disease at some other part of the body." Mangan emphatically states that this is unadvisable unless great care is exercised in its preparation. If it receives too much heat it is useless, and if too little heat it is dangerous. Possibly a water bath for two hours at a temperature of 60° C. may be a good way to prepare the pus for injection. The filtering method is according to Duncan and is the method I suggest to be adopted."

Doctor Crockett says: "Using Duncan's theory as a working basis." It would appear that he is using and appropriating it, for there is nothing new about the method he describes. Not even the advantages enumerated at the close of his paper, since these are mentioned in my article in the New York Medical Journal for December 12 and 21, 1912.

Book Reviews.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

This reference book to the health resorts of the British Islands is excellently gotten up and well arranged. Thus, it is really a handy book which carries out what the title promises. It gives all the information a physician could desire: Location, climate, indications, attractions in the way of recreation, etc., and also the chemical analysis and physiological action of the various waters, with mode of employment and therapeutic action, indication, and contraindications. The addendum with maps and index concludes a very useful book.

The thirty-third volume of this new and important treatise on surgery by French authors is devoted to the subject of surgical injuries, deformities, and diseases of the extremities. It includes those of general surgical and orthopedic interest. The subjects treated are traumatism, infections, tumors, and congenital and acquired deformities of the upper and lower extremities. This combining of general and orthopedic surgery has a distinct advantage and emphasizes the fact that both the general surgeon and the orthopedic specialist should be familiar with the subject so arbitrarily divided between them by the prevailing practice of the day. The subjects are treated in minute detail and the author demonstrates a knowledge that could only have been gained by long experience at the bedside and in the operating room. There are more than 300 illustrations, most of them original, including many radiographs or outlines of x-ray plates. At the end of the various chapters a very complete bibliography is given, so that the reader can find more detailed descriptions in various monographs and special treatises. The book is thoroughly abreast of the times and represents not only the author's practical work in this field but also the results of research and special practice. He, however, prescribes a cordial reception not only among general and orthopedic surgeons but also among general practitioners, who should be familiar with the main aspects of this very practical field of surgery. The present volume is fully up to the high standard of the preceding thirty-two numbers of this great French work on surgery.

The author has acquired a great deal of valuable information in his official position as commissioner appointed by the government of South Australia to investigate the methods of medical supervision in schools in Great Britain, Canada, the United States, Germany, and Switzerland. The impressions received during his extended tour Mr. Steven has carefully noted, and we have thus a valuable work which brings out the methods adopted in the five countries visited, making comparison very easy. The book is certainly very instructive.

This excellent compendium deserves to have seen ten editions in twelve years. It helps to introduce the student to the subject of obstetrics and gynecology, and assists him in memorizing certain essential points in this branch of medicine. The size of the book makes it also very easy to carry and to refer to.

The author has succeeded in setting forth in a simple and untechnical way some of the hygienic requirements of school life, together with suggestions as to how such requirements can be put into practice. He has selected the most important topics, and discusses these more for the benefit of the busy teacher than for that of the specialist in school hygiene. But not only the teacher will receive new and fresh ideas, the physician and even specialist will obtain instructions and valuable advice. The book shows that its author is thoroughly conversant with the subject of which he treats.

This publication deals at some length with the relationship between the digestive system and the acute infectious fevers. The first portion discusses the etiologic importance of the digestive system. Under this heading are considered the changes in the intestinal flora, the decrease in the resisting power of the tissues, the simultaneous occurrence of digestive disturbances and inflammations by foreign organisms, and the changes of temperature that are brought about by the advance or retrenchment of the process, which is the longer, gives a very good presentation of the symptoms in acute infectious diseases that arise from gastrointestinal disturbances. The different portions of the alimentary tract are dealt with individually, in addition to the liver, pancreas, spleen, and peritoneum. The author, among other things, calls attention to the valuable information that may be obtained from a careful examination of the stools. In the pages of this book there is to be found much that is useful.
United States Public Health Service:

Official list of changes in the stations and duties of officers serving in the United States Public Health Service for the seven days ending June 25, 1913:

Francis, E., Surgeon. Granted six months’ leave of absence, without pay, from July 1, 1913.

Frost, W. H., Passed Assistant Surgeon. Directed to proceed to Philadelphia, Pa., and continue in Washington under the Director of Health, relative to certain typhoid conditions in that city.

Hollman, H. T., Acting Assistant Surgeon. Granted thirty days’ leave of absence from June 18, 1913, and will proceed to the Surgeon General’s Office.

Kuhn, C. F., Acting Assistant Surgeon. Granted six months’ leave of absence, without pay, from July 4, 1913.

McLaughlin, A. J., Surgeon. Granted six months’ leave, without pay, from July 1, 1913.

Markoe, W. W., Acting Assistant Surgeon. Granted sixty days’ leave of absence from July 1, 1913.

Nauty, C. W., Jr., Acting Assistant Surgeon. Granted thirty days’ leave of absence from July 1, 1913.

Porter, J. Y., Quarantine Inspector. Directed to proceed to the Tampa Ray Quarantine Station to investigate cause of fire, repairs and equipment needed, and to fix responsibility.

Stevenson, J. W., Acting Assistant Surgeon. Granted three months’ leave of absence, without pay, from June 16, 1913.

Army Intelligence:

Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Army for the week ending June 28, 1913:

Coe, Henry C., First Lieutenant, Medical Reserve Corps. Ordered to active duty for the period from June 28 to July 25, 1913, for service at the Canton, Ohio, for the purpose of observing the camp of instruction of sanitary troops of the organized militia to be held at that place June 22 to 29, 1913, and upon completion of this duty will return to his proper station.

Duchert, B. H., Major. Relieved from duty at Fort Sam Houston, Texas, about July 1, 1913, and will proceed to San Juan, P. R., for duty.

Ghrist, Harry L., Major. Ordered to active duty at the Canton, Ohio, for the purpose of observing the camp of instruction of sanitary troops of the organized militia to be held at that place June 22 to 29, 1913, and upon completion of this duty will return to his proper station.

Peck, Luke E., First Lieutenant, Medical Reserve Corps. Upon arrival in the United States will proceed to Fort Meade, South Dakota, for duty.

Shields, William S., Captain. Relieved from duty at Columbus Barracks, Ohio, and assigned to Fort Omaha, Neb. Will proceed to Fort Meade, Major Texas City, Texas, for duty with the Second Division.

The following officers of the Medical Reserve Corps have been ordered to active duty for the encampment at Gettysburg, Pa., June 28 to July 10, 1913, and on the completion of duty will proceed to Parkerton: Herrera Press, W. S. Cornell, George C. Kieffer, Walter E. Lee, George C. Beach, Jr., William S. Magill, Meyer M. Eckert, William E. Fitch, Howard Hume, Joseph V. Klauder, Charles B. J. Mittelstaedt, Raynond W. Wilcox, S. Mer- dith Strong, George C. Leet, Dr. Crampton, Arthur R. Jarrett.

Navy Intelligence:

Official list of changes in the stations and duties of officers serving in the Medical Department of the United States Navy for the week ending June 28, 1913:

Butts, Heber. Passed Assistant Surgeon. Detached from the Naval Hospital, Canacoo, P. I., and ordered to the El Cono.

Camerer, C. B., Assistant Surgeon. Detached from the Denver and ordered to the South Dakota.

Deaths:

Connor—McAlduff. In Boston, Mass., on Wednesday, June 19, 1913, Dr. George A. Connor and Miss Mabel F. McAlduff. Davis—Geesey. In Atlantic City, N. J., on Monday, June 23d, Dr. Bryon G. Davis and Miss Naomi Geesey.

Haeusker—Cook. In Boston, Mass., on Wednesday, June 25th, Dr. William P. Hammond and Miss Sally J. Lawson. Hauss—Cozners. In Cincinnati, Ohio, on Wednesday, June 18th, Dr. Augustus P. Hauss, Sr., of New Albany, Ky., and Miss Roberta V. K. Cozners.

Married.

Connor—McAlduff. In Boston, Mass., on Wednesday, June 19th, Dr. George A. Connor and Miss Mabel F. McAlduff. Davis—Geesey. In Atlantic City, N. J., on Monday, June 23d, Dr. Bryon G. Davis and Miss Naomi Geesey. Haeusker—Cook. In Boston, Mass., on Wednesday, June 25th, Dr. William P. Hammond and Miss Sally J. Lawson.
LONGEVITY AND REJUVENESCENCE.\textsuperscript{*}

By I. L. Nascher, M. D.,
New York,
Professor of Geriatrics, College of Physicians and Surgeons, Boston.

Single celled organisms like the amebic possess potential immortality. When, however, two or more cells of different varieties combine to form a complex organism their diverse activities, reacting upon each other, disturb their mode of existence, sooner or later causing the death of the cells and the consequent death of the organism. So uniform is this procedure that like organisms have a like life history and a like duration of existence. If in addition to this fact we accept the theory of tissue cell evolution, that the cells of the tissues pass through evolutionary stages, that at one stage they are best suited to their environment and available nutrition, and the tissue which they form is then in its most perfect state, that succeeding generations of cells become gradually less and less fitted for their environment and nutrition and reproduce fewer and still more imperfect cells, we can form a basic conception of senescence and death.

Various formulas have been devised to estimate the normal duration of life in the animal kingdom, but none has a universal application or will apply to the human being. Buffon’s formula, seven times the period required to attain growth, would make the normal duration of life of man over 200 years. Flouron’s formula, five times the period required for the consolidation of the shafts and epiphyses of long bones would place the normal duration between 75 and 125 years. Flouron divides life into two periods, development and decline.\textsuperscript{3}

A more rational estimate of the duration of life is based upon the duration of the periods of development, maturity, and decline, since these in man are or should be fairly equal in length, and each is broken about the middle by a critical period or climacteric. While growth in height ceases about the twenty-first year, the body continues to grow in other dimensions, and the organs continue to increase in size and in functional activity until about the thirtieth year. About this time the brain is heaviest and fills the skull, the lungs have their greatest respiratory capacity, and the heart has reached its limit of normal growth. The bones are larger at thirty than at twenty-one, and we need a larger hat, larger shoes and gloves, and a larger suit of clothes at thirty. Any further increase afterward will be due to fat accumulation and not to bone growth. The vertebrae are larger at thirty, but, as I have explained in a former paper, when the body is erect the downward pressure upon the intervertebral disks, which are of uneven thickness, forces the spinal column into curves. As the pressure is greatest where the disks are thinnest, anteriorly in the dorsal region and posteriorly in the cervical and lumbar regions, the opposite side of these disks are relatively expanded, and we have, in consequence, the posterior curve in the dorsal region and the anterior curves in the cervical and lumbar regions. The body is longer on arising than on retiring, and there is an actual increase in length during a lingering illness which confines the patient to bed. This is due to the expansion of the intervertebral disks, when freed from the downward pressure.

The normal duration of the period of development is about thirty years, and this period is broken about the middle by the climacteric which we call puberty.

The brain begins to diminish in size soon after the thirtieth year, and about the same time the lungs diminish in capacity and functional activity, evidenced by a diminution in elimination of carbon dioxide, while the heart begins to hypertrophy. These changes are a departure from the state of perfect development, and this justifies Flouron’s division of life into development and decline. But for about three decades after development is completed there is stable metabolic activity, the catabolic and anabolic processes counterbalancing each other, and the harmonious relations between organs and between functions are maintained. This period of stable metabolic activity is maturity, or middle age, and is broken about the middle by the menopause in the female and the male climacteric in the male. The male critical period is not as marked as the menopause, and usually occurs later.

The individual who has been able to avoid the many incidental factors that contribute to and hasten senescence will not present subjective or objective manifestations of ageing before the end of the sixth or beginning of the seventh decade of life. The early subjective manifestations are usually aches and pains in joints (which the individual ascribes to rheumatism, but which are really due to arteriosclerosis), more rapid fatigue and a longer time required to recuperate, lessened

\textsuperscript{*}Read before the Medical Association of the Greater City of New York, June 2, 1913.

\textsuperscript{3}Owing to the scope of the subject and the limited time I have been obliged to omit many statistics, explanations, and qualifications of statements that may appear dogmatic.

Copyright, 1913, by A. R. Elliott Publishing Company.
sexual virility, weakened memory, names of familiar persons and dates of familiar events being first forgotten; and one accustomed to mental labors notices that words and ideas do not come as readily as before, and whereas he may have been able to write or do other mental work for hours, he must now take frequent rests and divert his thoughts into other channels; otherwise his mind becomes confused. A lessened interest in the events of the day and the tendency to fall asleep at the sermon or lecture are both objective and subjective manifestations. The ageing individual may find that he needs glasses, that his hearing is not as acute as formerly, that he is becoming habually constipated, gets out of breath when going up-stairs, that he cannot stand the cold and that the cold shower gives him a shock from which he does not react as quickly as before. The objective manifestations hardly need description. The attitude of the senile stoop or slouch, the folds and wrinkles in the darkened, weather beaten skin, the gray and thinning hair, arcus senilis, contracted pupils, tortuous arteries and enfeebled prominent filled veins, the apathetic expression and generally sluggish mentality, and bodily movements are all interpreted by layman and physician alike. It is ageing, or the period of decline. There are numerous factors which hasten or cut short this period, but where these can be avoided the period of decline will last about as long as the preceding periods, and it will be broken about the middle by a critical period which I have described as the senile climacteric. This would make the normal duration of life about ninety years, divided into three equal periods, development, maturity, and decline; each broken by a climacteric.

The tendency to complete the normal cycle of life is inherent. The child born healthy possesses a potential force of vitality which should carry it through the periods of development, maturity, and decline to physiological death. Few complete the normal cycle, but an analysis of the causes of death in those who do not will reveal in almost every case some avoidable cause; either exposure, improper food, improper mode of life, including mental strain, insufficient sleep, etc., or else accident. It has been said that there never was an accident which might not have been prevented by foresight and prudence. The same may be said of diseases.

I will not burden you with a mass of statistics. Most of our statistics concerning longevity are based upon census figures which, Prinzling says, are very untrustworthy. More trustworthy are figures dealing with the causes of death, though wrong diagnoses and improper classification where complications existed leave a wide margin for error. Better methods of treating diphtheria, tuberculosi, and other diseases of the period of development, and a better knowledge of sanitation have reduced the death rate up to the age of thirty, forty-seven per cent, between 1880 and 1910. The enormous increase in deaths due to diseases of the heart, kidneys, and circulatory system and industrial diseases, during the period of maturity, has almost wiped out the advantages gained during the period of development. According to the 1910 report of the field secretary of the Provident Life Assurance Society of England, the death rate from diseases of the heart, kidneys, and circulatory system, including apoplexy, has increased 105 per cent. in the United States since 1880, while in England the increase in deaths from these diseases during this period was only three per cent.

That this enormous increase in deaths from diseases of the heart, kidneys, and circulatory system is due to what is usually called the strenuous life, is unquestioned. In a paper on The Strenuous Life, which appeared in the Medical Record in October, 1911, I endeavored to show that, as a result of this intense and excessive activity, the individual is deteriorating mentally and physically and his mode of life tends to shorten his years. Prinzling has shown that in Germany industrial activity and city life have an unfavorable influence upon the duration of life, notwithstanding the more sanitary conditions in the cities, and the same will probably hold good for the United States. According to H. Josse Johnson, the factors that tend to longevity are: 1. Heredity, 2. climate, 3. surroundings, as occupation, housing, education, etc., 4. average height and weight, 5. chest development and capacity, 6. proportion, i.e., distribution of weight. The last three factors may be omitted from further consideration, as they are not universally applicable. The extremes of height and weight are rarely found, the chest development can be increased; yet Johnson doubts the advantage of the military chest from an insurance standpoint, and improper distribution of weight is itself pathological. His conclusions concerning climate, that the increase of mortality is greater as the heat increases, and, consequently, less conducive to longevity, is not borne out by statistics, for in Europe Bulgaria has the largest proportion of persons over eighty-five, while Germany and Finland have the smallest proportion.

Heredity is undoubtedly the determining factor in longevity. But I cannot endorse the statement often made that there is a racial tendency toward longevity. In support of this statement the longevity of the Jews is often pointed out. This holds good only so long as they adhere to their religious laws. When they depart from these laws they are subject to diseases which rarely attack the strict adherent to the Mosaic sanitary code. One of the most important of these laws is that relating to kosher meat. The meat must be used within three days after the animal is slaughtered, the hind quarters are rejected, the bloodvessels are taken out, and if any carcass is found diseased it cannot be used. There are numerous other laws of a similar nature which have for their purpose the prevention of the introduction of food in process of decomposition. There is probably no one factor more potent in causing early arteriosclerosis, and consequent precocious senility, than the introduction of food which rapidly decomposes in the stomach and intestines, as cold storage foods do. The Jew who departs from the strict kosher dietary may still possess the inherited influence of hereditary longevity, but one or two generations will suffice to

1I desire to express my thanks to the statistical bureau of the Metropolitan Life Insurance Company for statistics and other matters furnished me for the preparation of this paper.

NASCHER: LONGEITY AND REJUVENESCENCE.

virgin and the multigravid woman. Thoma’s histomechanical theory. Owing to the unceasing activity of the bloodvessels, the constant stretching and relaxation of the muscular fibres of the media cause a loss of their tonicity and dilatation of the walls of the vessels, with consequent slowing of the current. Demange’s histopathological theory. Owing to the ceaseless activity of the vasa vasorum they become irritated and finally inflamed, their calibre is diminished, and an insufficient blood supply is furnished to the larger vessels. Durand Fardel’s vital theory. The purpose of the organism is to reproduce its kind, and it has an opportunity to do so during the period of sexual virility. When that period has expired, further metabolic activity is in the direction of destruction of tissue. Naunyn’s deficient heat regulation theory. That the heat regulating centres become weakened, muscle activity is lessened, less blood is required to repair the diminished waste, the circulation is weakened, and organs and tissues do not receive sufficient blood for their nutrition. Metchnikoff’s tourn theory. That the products of intestinal decomposition are absorbed, and carried in the blood they act as irritants to the lining membrane of the vessels, causing endarteritis and subsequent arteriosclerosis. Horsley’s thyroid metabolism theory. That the thyroid gland becomes weakened in its functional activity and metabolism is disturbed. Lorand’s glandular theory is similar to Horsley’s theory, but he includes the thyroid, suprarenal, and pituitary glands. He ascribes ageing to a slowing of the processes of oxidation, defective activity of organs which should destroy and eliminate waste, and consequent autoinfection from such toxic material, and hyperplasia of connective tissue. Canstatt’s cell theory. That the cells of the body have a limited duration and when they die the tissue dies. Minor’s cell theory. That there is a gradual increase in the protoplasm of the cell, its activity being thereby altered. Tissue cell evolution theory. This has been mentioned in the course of this paper. Pneumokoniosis theory. That the constant inhalation of dust diminishes the aerating surface of the lungs, causes impaired aeration of the blood, diminishing its capacity for carrying nutrition to tissues and carrying away waste material. Defective metabolism theory. It holds that with advancing age there is instability in the character of the blood with gradually increasing amounts of urea and calcium and diminution in other salts, due to disturbed metabolism and elimination. This theory accounts for the increased viscosity of the blood, and the consequent impairment of the circulation, causing deficient nutrition of the tissues. The excessive calcium is deposited in abnormal situations, in bone, causing calcification with the greater tendency to fracture, in cartilage, aiding in ossification, in arteries, causing arteriosclerosis, in joints, causing tophi, etc.

This theory would bear out the theory of tissue cell evolution if it could be shown that the late cells

destroy this influence under the more immediate influence of improper food and improper living. We must remember that good heredity implies healthy parents, and healthy parents will beget healthy children. Such parents do not transmit any special quality to produce longevity. As I said before, the tendency to complete the normal cycle of life is inherent in every living creature. This tendency is weakened by inherited disease or predisposition to disease. Environment, including mode of life, is the immediate factor in determining the length of life of the individual, yet persons have grown old under most insanitary conditions, having evidently acquired a tolerance to such conditions. When the crusade for fresh air and open bedroom windows began, many persons who were accustomed to sleep in close, windowless bedrooms became afflicted with laryngeal and bronchial troubles when they first attempted to sleep with open windows. A change in diet, sleeping hours, even in dress, may have unfavorable results, though such change be in itself more healthful. There is no law applicable to idiosyncrasy, and what will injure one may be harmless or beneficial to another; and we must be content with a few generalities regarding the effect of environment upon longevity. More women reach old age than men, but this is probably due to their more protected lives and less exposure to the stresses, strains, and casualties of industrial life. Where women are exposed to these to the same extent as men, as happens in Servia and Bulgaria, fewer women reach old age. In a recent article in the Medical Record, A. H. Stewart ascribes their greater tenacity of life in the United States to a constitutional difference. Most persons who have reached old age were sparse eaters and led outdoor lives. Most old men were smokers and drank alcoholic liquors. Most old persons came from agricultural districts and were married, and nearly all were actively engaged in their labors until shortly before death. On the other hand, those who retire from active business early soon go into rapid decline. Insufficient sleep prevents complete repair and hastens degenerative changes, and the same applies to irregular hours, irregular meals, and irregular means of livelihood. Mental stimulus in work and recreation prevents mental depression, with consequent inaction and slowed circulation. This slowed circulation causes impaired nutrition of the organs and their degeneration.

Numerous theories have been advanced to account for the process of senescence. While there is undoubtedly a determining cause, it is probable that many factors are involved and that most of the supposed causes which form the basis of the theories advanced are incidental or essential aids to the determining cause. Which of the many causes is the determining one is uncertain; possibly there are several which must act together, or different causes may act in different cases. I will mention briefly some of the theories. The old mechanical theory of wear and tear has been discarded, as organs and tissues undergo the same smile changes whether excessively, or rarely employed. This is seen in the brains of the idiot and the sage and in the uterus of the
have a greater affinity for lime than earlier cells. The retention of lime in excess is the first step in senescence. If we can eliminate carefully the causes upon which these theories are based we will find that most of them can be controlled to some extent. Auto-intoxication, upon which Methchnikoff's theory is based, is partly controlled by the measures he has advocated, proper food and the lactic acid bacilli. Any cause which produces increased heart action and consequent hypertrophy will increase vascular activity, with more rapid loss of toxicity of the muscular fibres of the vessels. Any disease associated with toxemia, such as syphilis, diabetes, gout, rheumatism, alcoholism, will cause endarteritis, with consequent degeneration of the vessels. The glandular theories of Horsley and Lorand do not explain the cause of the initial change in the glands, and the only rational explanation for the initial change is a change in the nutrition, caused by some alteration in the blood. It is possible that the administration of the extracts of these glands will improve metabolic activity in the aged.

There are many factors which are recognized as contributing to the production of early ageing, through causing arteriosclerosis or other tissue degeneration. It is hardly necessary to mention improper living, improper food, excessive food, insufficient sleep, mental strain, etc. Factors not generally recognized, having a deleterious effect upon the organism, are, the fine, rapid vibrations of motor driven vehicles causing irritability and neurasthenia, quickly moving elevators causing cerebral anemia when going up and hyperventilation when descending, the eyestrain produced by the flickering of moving picture machines, the earstrain and mental strain caused by listening to the telephone, ignoring at the same time surrounding noises, the many little shocks and momentary frights when crossing streets where there are many moving vehicles, and when avoiding other dangers, the startling city noises, etc. These all affect the nervous system, hastening its breakdown and degeneration.

Taking up rejuvenescence, we must consider two kinds of impossibilities, the absolute, which from their nature can never be possible, and the temporary, which are impossible at present because our present means are inadequate or our present measures are faulty. Rejuvenescence in the sense of restoring youth to old age is an absolute impossibility. But there is nothing inherently impossible in the idea that we can stimulate the functions of senile tissues, increase metabolic activity, control some of the factors that contribute to senescence, and improve the mentality and physical appearance of the aged. Some of these have been done, though not for the specific purpose of rejuvenescence. I have on several occasions spoken of the beneficial psychic influence of flattening, the stimulation of the sense of pride, especially pride in appearance, sexual relations, with young mates, and social intercourse with the young generally. I will only refer to the marked change in personality of the old man who goes a courting or who takes a young wife. Social intercourse with the young exerts a powerful rejuvenating effect, and this has been recognized in parts of Switzerland, where dependent aged persons are sent to board with families in which there are young persons. The Nestor of our profession once said his association with the young tended to make him feel young. The improvements in the general appearance has a profound psychic influence, not only directly through the stimulation of the sense of pride in appearance, but indirectly through the flattering comments which it arouses. This important measure is generally neglected by men, yet aside from the beneficial psychic influence, for esthetic reasons alone the old man should endeavor to make himself appear as attractive as possible. This does not mean that he should resort to the artificial devices that middle aged and elderly women employ to enhance their charms. It does mean that the old man should stimulate the surface circulation by means of baths and massage, remove wrinkles and folds by inunction with animal fats, try to stimulate the growth of hair on the head and remove hair from abnormal situations as the ears, use a cane and wear braces to overcome the tendency to stoop, employ harmless cosmetic measures to improve his appearance, and, above all, observe a sense of neatness in dress. Instead of decrying such a course as vanity, it should be encouraged as a laudable effort to maintain a youthful spirit. Many of the factors that contribute to senescence can be controlled in a measure through change in the mode of living, in food, in occupation, means of transportation, and environment. Pneumokoniosis cannot be entirely prevented, but it can be retarded by living in a dust free atmosphere, as on the seashore. A comparison between the lungs of an old sailor and an old resident of a city in which soft coal is used—the former light gray, the latter black—will show the disastrous effect of the constant inhalation of dust and smoke.

Besides the hygienic measures, there are some medical measures which retard the senile changes and stimulate the functions of senile organs. The skin can be kept soft and moist through the occasional use of an animal fat containing a small amount of water. The fats most suitable are hydrous woolfat and sweet butter, both of which will take up a small quantity of water. Vegetable oils are not so readily absorbed, yet they are frequently used. The virtue of almond meal, which is extolled for this purpose, lies in its oil content. The most important medical indication for improving the general condition of the aged individual is the increased elimination of calcium or the restriction of its introduction. As the lime is derived from the food, a lime free diet has been advocated; but there are few foods free from lime, and the artificial abstraction of the lime diminishes or destroys the nutritive value. The iodides have been recommended, but they have no influence upon the total amount or the elimination of the calcium salts. Trueneck's serum has been used upon the theory that by increasing the quantity of the other salts, the proportionate relationship between the various salts will be reestablished and the damage done when one is in excess, will be overcome. Weil has shown that in arteriosclerosis there is a deficiency of salts in the blood, the lime having been de-
posit ed in abnormal locations, the other salts being eliminated. Trueneck's serum has been found to relieve symptoms in some cases of arteriosclerosis while it was used, but it did not increase the lime elimination, while the elimination of other salts is increased. A few years ago I began to use the red, amorphous phosphorus as a substitute for the ordinary yellow phosphorus, and in a paper on Senile Debility, published in the Medical Record in January, 1911, I stated that in grain doses it had no appreciable effect. I found, however, that it was eliminated in the form of amorphous phosphate of lime, and by giving larger doses, larger amounts of this salt were eliminated. In four senile cases which I was able to follow closely, in which this substance was given for a period of several months, there was a lowering of the blood pressure and relief from the distressing symptoms of arteriosclerosis. In three of these cases vertigo was a prominent symptom, and this was relieved, while in one case there has been no recurrence of vertigo in eight months. In all four cases there was a general improvement in the physical condition. Time does not permit me to go into detail in these cases, and I must content myself with this general statement. Amorphous phosphorus, besides its constitutional effects, will increase the elimination of calcium through its combination with the lime and its own elimination. Amorphous phosphorus will not rejuvenate the aged in the sense that it will make an old person young. It will improve the physical condition and by employing, at the same time, a rational hygiene and those measures that will improve the mentality and the appearance of the aged individual it may be possible to make the old person look younger than he is and feel younger than he looks.

631 East 168th Street.

WOUNDS.

By Samuel Lloyd, M.D.,
New York.

Heiser, in his General System of Surgery, published in Nuremberg in 1718, says in his opening paragraph:

The principal end of physic is to prevent or relieve the disorders of the human body. This, the first physicians endeavored to effect by three means, either by food, medicines, or the application of the hand, or by all together. If the case required it, which method, reason and experience teach us, is absolutely necessary at this time: And of these three branches of this salutary profession, they called the first, diet or dietical, the second, pharmaceutical, and the third, chirurgical. For since the end of physic could by means be always obtained by diet and medicine alone (though they are of very great service in preserving and restoring the health of mankind), but manual operation is also found sometimes to be absolutely necessary, it is plain, therefore, that this branch of physic, which is called surgery, is very necessary to mankind; more especially as it appears that by this means many grievous disorders are relieved, as wounds, fractures, luxations, and several others, where diet and medicine would afford very little and sometimes no help at all. But that the excellence and necessity of this art may appear more clearly, it may be necessary to observe that other arts only conduce to the convenience of life, but the art of surgery is frequently necessary for the preservation of life and the continuance of health, the most valuable treasure we can be possessed of. This necessity appears more particularly in dangerous wounds received in war, skirmishes, or sieges, where many brave men must necessarily perish from loss of blood and other causes unless they are restored and snatched, as it were, from the brink of death by the skill of their surgeons. And no doubt the better opinion the soldiers conceive of their surgeons, the more spirits they have for the combat; having good confidence that the wounds they receive shall be properly treated and their lives preserved.

This was illustrated in the career of that great surgeon of the sixteenth century, Ambrose Paré. During the siege of Metz, in 1552, which was defended by the Duke de Guise, two hospitals had been established, but the mortality was so great, and the incompetence of the surgeons so evident, that the soldiers became convinced that the sick and wounded were being neglected, and lost heart. The Duke then sent to Charles V., saying that the sword could hold out for ten months, but needed medicine. Paré was sent for, supplied with money, and medicines, and finally succeeded in gaining entrance to the beleaguered city. He entered Metz at midnight of the 8th of December. Sixteen years as a military surgeon had made him known to most of the officers and many of the common soldiers, and when he was presented on the bulwarks the next morning he was received with shouts of: "We shall not die, even though wounded; Paré is among us!" and it is generally believed that it was to the presence and the influence of this single man, a noncombatant at that, that the city owed its salvation. So, too, it is related of Baron Larrey, surgeon-in-chief to the Grand Army, and whom Napoleon I. called the most virtuous of men, that during the Russian campaigns, when the flight of the French army was arrested by an almost impassable stream, he was seized by the soldiers and carried across to the other side, that he might be able to minister to their wounded.

Aetius (500-550 A.D.) quotes Leonidas of the first century in describing the surgical treatment of cancer of the breast, as follows:

In the treatment of those cancers that arise upon the breast I rely entirely upon surgery, which is done thus: I make the patient lie upon the back, then I cut upon the sound part of the breast above the cancer, and burn in the incision with a redhot iron until a crust is formed, sufficient to arrest the flow of blood; I immediately incise again and dissect up from the deepest part of the mamma, and again burn the incised part; and after this I repeat the cutting, following it with a redhot iron sufficient to arrest the hemorrhage. The first burning is for the arrest of the hemorrhage, but afterward the burning is for the removal of every vestige of the diseased tissue. But in men, also, when cancer arises in any part of the body situated less deep in the breast, the entire operation is performed without the cautery, for in such cases it is sufficient to amputate to the sound parts, as there is no danger from hemorrhage.

This statement is interesting at the present time for two reasons: First, it illustrates that the cautery was in use then, as now, for the control not only of the hemorrhage but for the destruction of the malignant tissue. At present, not only is active cauterization employed, but fulguration and electrical applications, as well as the knife, are used to achieve the same results. Second, it illustrates the incomplete method of removal of the cancerous breast which was in vogue for so many centuries and even up to the time when the present speaker
was a student of medicine, and which led the late Doctor Gross, of Philadelphia, at that time the master of American surgery, to say that he had never cured a case of cancer of the breast and that he only operated to alleviate the pain and relieve the anxiety of the patient. How different are conditions now, when surgeons the world over recognize the precancerous stage, and save by operative means from sixty to seventy per cent, of the patients who seek treatment early enough.

This method of treating hemorrhage continued up to the time of Paré. The introduction of the ligature by this surgeon may be considered as the first epoch of the modern treatment of wounds. At the time of Paré the method of treating hemorrhage was by means of a redhot iron, and this was the only method described by him in his work published in 1552—just a thousand years after the work of Aetius. But in 1504 he had adopted the ligature, and then he speaks of the cauterization of wounds as "a thing very horrible and too crude to mention," while he says of his previous employment of this method: "Whereof I am ashamed and aggrieved. In conclusion, I counsel the young surgeon to abandon this miserable way of burning and roasting."

At this time wounds were treated by filling them with and pouring over them boiling hot oil, and Paré had for years followed his predecessors in this respect. In his Voyage to Thurian, in 1539, he says:

"I took courage to doe as they did. At last I wanted oyle, and was constrained instead thereof to apply a diges of volokes of eggs, oyle of roses, and turpentine.

In the night I could not sleepe in quiet, fearing some defect in not cauterizing; that I made me rise very early to visit them, whereby my expectation I found those to whom I had applied my digestive medicine to feel little pain, and their wounds without inflammation or tumor, having rested reasonable well in the night, the others to whom was used the sayde burning oyle, I found them feaverish, with greater paine and tumor about the edges of the armes, at whose end I resolved with myselfe never so cruelly to burne poore men, wounded with gunshot. Being at Thurian, I found a chirurgeon who had the same rules as I, and used for the curing of wounds of gunshot, into whose favor I often went to impart myself, to have the receipt of his balmes, as he called it, wherewith he dressed wounds of that kind; and hee held me off the space of two yeares before I could draw the receipt from him.

In the end, by gifts and presents, he gave it me, which was this: he boiled young whelips, new pupped, in oyle of lilies, prepared with earthwormes, with turpentine of Venice. Then was I joyful, and my heart made glad, that I had understood his remedy, which was like to that I had obtained by great chance. See, then, how I learned to dresse wounds made with gunshot, not by books."

Thirty or forty years later there flourished in England William Close, a naval surgeon, and one of her Majesty’s chirurgians, who published in 1591 a book under the title, A Practical Practice for all Young Chirurgians Concerning BURNINGS with Gunpowder and Wounds, made with Gunshot, Sword, Halberd, Pike, Lance, or such other, in which he speaks of "the manner and order of taking off a mortified and corrupt leg or arm, which cometh oftentimes by reason of wounds made with gunshot, etc."

In one place, he says:

"Then, as I have said, that oftentimes it happeneth that by reason of the evil accidents which follow wounds made with gunshot, that the whole member cometh to gangrene, sideratio, or spleenous, so that we are many times constrained forthwith to make a speedy dispatch to cut off the member which shall be done as Gale and others very skilfully appointed in the whole and sound parts. The things being observed, then, through the assistance of Almighty God, you shall lacke accomodation by your industrie and diligence . . . and after that his body be well prepared and purged (a precaution taken even at the present time) then the same morning you doe attempt to cut off the member, be it leg or arm. Let you have, some two hours before, some good comfortable candell or other broth, according to the discretion of the physician or chirurgeon, only to corroborate and strengthen his stomach; and in any wise omit not that bee or shew which ministered unto them some principles concerning patience in adversity, to be made by the minister or preacher. (An admonition not entirely neglected to-day.) And you shall likewise advertise the friends of the patient that the work which you go about is great and not without danger of death, for that many accidents and evil symptoms doe happen which in such cases many do admit no cure, All which being considered, then ordaine the night before some good defensive, and let it be applied two or three times about the member (our present practice)."

After giving full directions for the amputation and the formula for his restrictive powder, he says:

"Take of this powder as much as will serve your turne, and mixe with the said powder the hair of a lare and the egg of eche, by which means you may induce the hare’s haires be the whitest and the softest that is taken from under the belly of the hare and cut so fine as possible may be, and with the same powder let all be mixed together and so be brought to a reasonable thickness. And after that be cut off the endes, and given to the patient in like manner made for the purpose three or four small bolsters or buttons, fashioned in the upper part like a dove’s egg or as a sugar loafe button, flat in the bottom to the compasse of a French crowne or round warders, as aforesaid, and these yee shall make of a very fine tow, according to art, wrought up in water and vinegar; wherupon you shall apply some part of the restrictive, being mixed, as I have before declared. But yee shall further note that this is a chirurgeon in France, with whom very learned and skilful men, counselleth thus, to drawe out the veins and arteries with an instrument called a raven’s bill, and then they tie those vessels with a double strong ligature or thread, and so safely staye the bleeding. But to that, I never taught this order by stiching the veins and arteries. I will leave it as before said, and proceed with mine own approved practice. Place upon the veins the round endes of the small buttons, and upon them presently lay on a round, thick bed of towne, made up in water and vinegar, so as they may be fill’d into the veins, and you can guess it to the compasse of the stumpe or member, that is taken off, and thereon place the restrictive; etc.

We have selected these quotations because they illustrate the treatment of wounds at the period of the first epoch, and show where some of the present popular method of treatment of wounds originated. It is interesting to note that Shakespeare was cognizant of some of the methods handed down by tradition, and still employed. Thus, in “Midsummer Night’s Dream,” Act III, Scene i, Bottom exclaims: “I shall desire of you more acquaintance, good master Cobweb; if I cut my finger, I shall make bold with you”; and, again, the Second Servant in King Lear, Act III, Scene vii. says: “Go thou, I’ll fetch some flax and whites of eggs, to apply to his bleeding face. Now, Heaven help him.”

Even Homer, in the Ninth Century, B. C., wrote of surgeons and of wounds and their treatment. Thus in the Iliad we find him speaking of the sons of Æsculapius:

"Of two great surgeons, good Podallirius stands, This hour, surrounded by the Trojan bands, And great Machaon, wounded in his tent. Now wants the succor which so oft he lent,\n"
And then with the removal of 'deadly darts and stinging arrows' he sings:

"Patriotus, cut the forky steel away
And in his hand a bitter root he pressed.
The wound he washed, and styptic juice infused.
The closing flesh that instant ceased to grow.
The wound, to torture, and the blood to flow."

While Nestor exclaimed:

"A wise physician's skill, our wounds to heal,
Is more than armies to the public weal."

The second great epoch in the treatment of wounds came with the discovery of anesthesia. England and the United States divide the honor. In the former, chloroform was discovered, and still remains the favorite method of obtaining insensibility to the surgeon's touch; while the United States gave us ether, the safer of the two, and now almost universally employed in this country. These boons to humanity, discovered by Simpson in England and Morton in the United States, have made modern surgery possible, and robbed it of most of its terrors. Instead of a frightened, screaming, struggling victim, strapped to a table or held down by brute force, with a surgeon hurrying every motion to shorten the agony, we have now the peacefully sleeping patient and the surgeon, serene, calm, collected, with every faculty devoted to doing in a quiet and deliberative way what is best suited to each individual patient. Instead of the piercing shrieks of the anguished victim, the operating room is quiet, suited to painstaking, scientific work.

Hardly had the world become accustomed to anesthesia with all its benefits to mankind, than there appeared a poor chemist in Paris, the son of one of Napoleon's soldiers, a tanner by trade, who had developed to a high degree the deductive method of reasoning. Aided by the recently perfected microscope, he began to study the subject of putrefaction and fermentation. It was not long before he was able to prove that the change of wine to vinegar was due to the presence of a micro-organism which floated in the air. A cork of sterilized cotton sufficed to prevent its entrance into the bottle, and the wine did not change to vinegar. These conclusions were reached only after long study and acrimonious debate. On the other side of the Channel was a Scotchman, whose father had long been a patient and intelligent worker with the microscope, who brought to the study of medicine not only a trained mind, but a desire to delve into the cause of things. Studying with his microscope, and at the same time walking his wards in the surgical division of a hospital at Edinburgh, he wondered from time to time what produced the suppuration and all the other diseases of wounds that infected every hospital the world over. He had for a long time been convinced that wound inflammation and its consequences, erysipelas, pyemia, septicemia, hospital gangrene, etc., were due to the chemical changes which occurred in the putrefaction of blood and blood serum; but it was not until, by chance, perhaps, he happened to read of Pasteur's experiments, in 1860, and the following few years, as published in the Comtes rendus, that he began to realize that there might be agencies extraneous to the human body that would set all these diseases in motion. This was the third great epoch in surgical history; the revolution was on. At this time the state of surgery can best be described in the words of our own Keen, who, in the Medical and Surgical History of the War of the Rebellion, says:

The surgeon approached the operation with the clean hands of a gentleman; he usually wore an old coat covered with the dried blood spots from previous operations. His fingers nails very likely were long, and no special attention was given to them. The instruments were taken out of a velvet lined case, and were as clean as ordinary table knives would be. The operation was done without any preliminary cleansing of the skin other than to remove any visible dirt. If the knife happened to fall on the floor, it was picked up, rinsed in a basin of ordinary water, and used as it was. The marine sponges then always used, were washed clean in ordinary water, and used over and over again, even after being saturated with foul pus. The bloodvessels were tied with ordinary silk; one end was cut short, the other end hung out of the wound. After the amputation of a fleshly thigh I have often seen twenty-five or thirty such ligatures gathered into two bundles, one at each end of the wound. The flaps were then sewed together with an ordinary needle and thread, and the stump dressed first with an old rag or scraped lint spread with some simple grease. Over that would be placed some other rag or cotton, or other dressing, and finally, a bandage. During the Civil War these greasy dressings gave place to simple cold water dressings. By the second day the patient would begin to have considerable fever. By the third or fourth, the temperature would rise. If anything worse occurred, the surgeon (if he was not in general use in that early day) to about 103°, 104°, or 105° F. Then we would poultice the wound. Every few hours the patient would be disturbed—a new dressing put on to replace the old on now cold, foul, and ill smelling; and by this time bathed with pus. I have often seen the pus escaping by the tablespoonful, and the wounds alive with squirming maggots, resembling chestnut worms. By this time also it was hoped that the silk ligatures with which the arteries had been tied had literatureally rotted loose, and each of them was gently pulled on, to the discomfort of the patient. Care was taken that the ligatures with knots tied on them (in order to distinguish those which secured the large bloodvessels) should not be pulled on severely until probably the tenth or twelfth day. Meantime, the patient was tossing about the bed with pain, with thirst, without appetite, without sleep except such as morphine would secure. This, at the same time stirred up all the secretions, produced terrible vomiting and other evils. By about the tenth to the fourteenth day, suppuration having been fully established and quantities of pus pouring from the wound, the fever would subside and the wound begin slowly to heal. Of course the healing could not complete until the ligatures were still protruding from the wound. Sometimes they did not become detached for even months or years, but more commonly all of them would rot loose in from ten days to three weeks. When the silk ligatures on the large bloodvessels came away, if the healing process had formed in the large bloodvessels a firm clot which had become adherent, and so to speak, corked it up—all went well. But, as very frequently happened, when the ligature and the root end of the artery were pulled off, and there was no clot to act as a stopper, secondary hemorrhage followed. This often came on after the patient's wound had been dressed, and the surgeon had left, and if so, it was likely that the future had been forecast. Everything wrong would either be the gasping for breath of the patient, or his moans and cries, or sometimes by the blood, which had not only saturated the mattress, but had even appeared in a pool on the floor. How fatal such hemorrhage was will be seen when it is stated that 2,235 cases of hemorrhage in the Civil War, 61.7 per cent. of the patients died. A large majority of the wounds were followed by erysipelas, lockjaw, pyemia, septicemia, or hospital gangrene.

The latter at times was so common and caused such ravages that, as Keen says, "it became a veritable plague." To-day, I doubt if there are any surgeons who have entered practice since 1880 who have ever seen a case. This disease has been prac-
tically wiped out of existence. In 2,503 cases of gangrene during the Civil War, 1,142 died. There were 505 cases of tetanus, with 451 deaths; pneumonia claimed 2,818 cases, of which 2,747 died; of 2,382 wounds of the knee joint where amputation was performed, 1,212 of the patients died; while out of 973 similar wounds, where amputation was not performed, 91 succumbed. Compound fractures were exceedingly serious, two out of three dying from some form of infection. Lister's discovery of the animal ligature, thus enabling us to close our wounds completely, added the needed finish to Paré's great discovery. Perhaps it is not right to say discovery, for the ligature had been employed before Paré, and had fallen into disuse; but he made it popular, and by the force of his example compelled its adoption. Our Civil War was but just over when Lister published his first paper, which appeared in the London Lancet of the 16th of March, 1867. In this he said: "We find that a flood of light has been thrown upon this most important subject by the philosophical writings of Monsieur Pasteur, who has demonstrated by thoroughly convincing evidence that it is not to oxygen or any of its gaseous constituents that the air owes this property, but to minute particles suspended in it, which are the germs of various forms of life long since revealed by the microscope, and regarded as merely accidental concomitants of putrescence, but now shown by Pasteur to be its essential cause, resolving the complex organic compounds into substances of simpler chemical constitution, just as the yeast plant converts sugar into alcohol and carbonic acid.

The treatment of wounds, therefore, at the present day, is no longer the simple matter that it was in the olden times. The wound must be carefully cleansed and the surgeon's hands prepared by careful scrubbing and protected by sterilized gloves to prevent any possible infection from that source. All instruments must be boiled for twenty minutes, and all dressings sterilized by steam under pressure. If pus appears to-day, we know it is due to a specific germ, and the surgeon seeks, not only to find the organism, but to ascertain if possible what error of technic allowed its entrance into the wound. Sometimes the germ is already present in the patient himself, and only makes known its presence when the injury provides the proper soil for it to grow and develop. In these cases, often, in spite of all that can be done, a general blood poisoning develops, but nowadays the surgeon most successfully meets this serious calamity by means of his serum or vaccine, one of the beneficent results of experiments on animals.

The first consideration in the treatment of wounds is the arrest of hemorrhage. In small and comparatively superficial wounds this may be done by simple pressure, but in more extensive and deeper cases it is often necessary to enlarge the incision and secure the bleeding vessels. It is fair to assume that all accidental wounds are infected, and therefore a question of primary importance is the proper cleansing of the whole involved area. The greatest mistake usually made by people in handling cuts or incisions is by sticking them together by means of a piece of sticking plaster or sealing them up so that the natural serum thrown out by nature cannot escape, and any infection that might be carried out by that exudation is sealed up in the wound. It is very important that the wound be put in proper condition for healing at the primary dressing, if possible. It is also important to determine whether nerves, arteries, tendons, or other important structures have been injured, and if so, to remedy the defect at once. It is also important to take into consideration what kind of infection is likely to occur. As it has been demonstrated in recent years that wounds from the toy pistols and from firecrackers, etc., are apt to produce tetanus or lockjaw, and the greatest care must be taken in these cases not only to provide for the proper dressing of the wound, but to watch carefully for the development of symptoms that would indicate the presence of the germ of this disease. In many cases it is better to give a dose of antitetanic serum at the time the patient is first seen.

The dressing of a wound is equally important. These dressings must be sterile and absorbent, and they must be fixed in place so that they cannot be torn off or displaced by the motions of the patient. They should be abundant and comfortable. Rest is exceedingly important, and if the wound occurs over a joint, or where an internal organ may be injured, rest is absolutely essential. An incised wound is one in which there is a clean cut made by a sharp instrument. If nothing but the skin and superficial tissues are involved, the only thing necessary is to stop the hemorrhage and apply a proper dressing. In many instances the margins of these wounds fall together and unite very quickly. If it is extensive or gaping, it is necessary to sew the margins together. Contused wounds are open wounds in which the edges are bruised. They are usually produced by blunt objects, such as stones, clubs, etc. In most of these cases it is necessary to put a sterile dressing into the opening of the wound, and then apply a copious dressing. A lacerated wound is one in which there is tearing or crushing of the tissue, making the margins irregular and ragged. Most of these cases have to be treated as open wounds. Stab wounds must always be considered as serious, for while the point of entrance may be very small, the injury to internal organs may be very great. Internal hemorrhage or puncture of the intestine, of the lung, or even of the heart, may occur, and must always be taken into consideration. Wounds of this kind should always be treated by a surgeon. An infected wound is the most serious condition that we have to deal with. The infection may be carried into the wound by the instrument producing it, by probing, if it is improperly done, or by the lack of surgical cleanliness in the dressing. When constitutional symptoms, that is, fever, chills, pain, and redness, appear in the case of a wound, it is certain that an infection has occurred, and then it is important that the case be referred to a competent surgeon, who will determine the type of infection and adopt the best means to control its progress. Neglect of an infected wound often leads to general blood poisoning.

Many diseases, formerly very common, resulting from slight wounds, have, since the days of Lister's discovery, been almost, if not completely, banished. Erysipelas, once so common, now is rarely seen:
THE RELATION OF INDUSTRY TO DISEASES OF THE HEART AND LUNGS.*

By John M. Swan, M. D.,

Rochester, N. Y.

There are certain essential conditions that must be present in order that animal life may be developed and maintained on the earth. Among these essential conditions may be mentioned a proper supply of air, the important element of which is oxygen; a proper amount of water; the presence of a proper food supply; and a certain degree of atmospheric temperature. In addition to these four essential elements, it is necessary that the living animal shall have alternating periods of rest and exercise. In order that human life may be developed and maintained on the earth these essential requisites for the maintenance and development of animal life in general are also requisite.

In particular relation to human physiology, it is necessary that the air furnished human beings shall be fresh and clean. That is to say, the air supplied to people assembled in houses, work shops, and places of amusement, must be renewed sufficiently to prevent the accumulation of poisonous materials passed into the air by these same human beings, and, in addition, it must be uncontaminated with dust, which may be injurious on account of its mechanical properties or which may contain microorganisms capable of producing disease. The water which is furnished for drinking purposes must be pure and uncontaminated with bacteria. The food supply must be nutritious and devoid of adulteration. Among the lower classes of animal's the amount of exercise taken and its relation to rest is regulated entirely by the instinct of the animal. In the human race, on the other hand, the amount of exercise taken and the relation that it bears to rest is regulated in some purposeful manner. Among the inferior races of mankind the purpose of the exercise taken is to supply the bodily needs of the individual and to afford amusement. As we ascend in the scale of civilization the purpose of muscular activity becomes more than that required for furnishing simply the bodily wants of the individual and for his amusement, and the efforts of member of the race, in one way or another, are directed to-ward producing objects of art, improved articles of clothing, better food materials in larger quantities, etc. Thus has developed, in the course of many centuries, the industrial enterprises that have now reached the highest development in the history of mankind.

In the last twenty-five years it has appeared that many of the individuals who are engaged in the production of the various products developed or perfected by modern industrial processes have become subject to serious diseases; and a great many of the more humanitarian members of the State, at the present time, have been seriously disturbed about this phase of our modern life. It must be remembered, however, that exercise, and hence industry, is a necessary element in the maintenance of life, and if industry is carried on under proper conditions it ought not to be productive of disease. Indeed, a recent writer in the American Journal of Public Health, has said: "Industrial disease is a misleading term, used for convenience only, or through ignorance, to indicate certain pathological states, the result of insanitation in industry. Industry itself is never necessarily unwholesome. Industrial processes, it is true, are objectionable and crude, oftentimes, but bad industrial conditions are always remediable."

In European countries a great deal of careful investigation has been made concerning the influence of certain industries upon the health of those engaged in them, and during this investigation it has been developed that certain occupations are dangerous occupations. Such, for instance, are occupations connected with the manufacture of lead and products containing lead; the manufacture of arsenic and materials containing arsenic; the production of mercury and articles in which mercury is used; and certain industries that are productive of dust of various kinds. We know that sometimes men employed in heavy labor, such as stevedores, porters, etc., will acquire serious heart disease from muscular effort. Clarinet players get emphyma of the lungs, coal miners get what is known as miner's asthma and bronchitis; stone cutters sometimes acquire a pulmonary disease which is known as fibrosis of the lungs, etc.; but the number of cases of such diseases is probably not great. When we study the incidence of disease which can in one way or another be connected with industry, our information concerning the number of cases and the class of cases which occur is very incomplete. In fact, in 1910, at a meeting of the First National Conference on Industrial Disease, the following resolution was unanimously adopted: "Resolved, that a special committee of five, who shall have power to add to their number, be herewith appointed by the president of the American Association for Labor Legislation, to call upon the President of the United States and present to him at an early date a carefully prepared memorial of facts and conclusions, emphasizing the urgent necessity and practical expediency of a national expert inquiry into the whole subject of industrial or occupational diseases; their relative degree of frequency in various trades and occupations, the causes responsible for their occurrence; the methods desirable and practicable for their prevention or diminu-

tion, and all other matters having relation thereto, including methods of amelioration and relief."

We must be very careful in our discussion of the effects of industry upon the lives of those engaged in it, that we do not convey the idea that we believe human beings ought not to have to work. Work is a necessary element in the life of man, and conditions in the world would be vastly more harmful to the human race if everybody could be idle than if everybody had to work. We can approach the subject of the effects of industry on the health of the worker from two points of view. First, in how far is the employer to blame for the cases of sickness among his employees; and, second, in how far are the employees themselves to blame for them. Let me refer for a moment to the elements that are necessary to life: Air, water, food, warmth. It is the employer's duty to furnish to his employees a place in which to work which is warm, which is well lighted, which is free from unnecessary dust, which is provided with the necessary toilet requisites, and which is furnished with an abundant supply of good drinking water. If the work comes under the head of dangerous occupations, the employer must see that all possible safeguards are provided to prevent the inhalation of dust and noxious vapors. He must see that his employees have an opportunity to wash their hands and faces before leaving the factory for their homes. It ought not to be necessary to enact a law to compel an employer to furnish reasonable protection to the men and women that work for him, nor should it be necessary to call his attention to the fact that certain processes of work in his factory may be injurious to the health of his employees.

On the other hand, the employer is responsible for his own health. He ought to know when he starts to work that he is well. He ought not to start to work with beginning disease in his lungs. If he does, and that disease develops, he ought not to say that it developed because he had to work. A man ought not to go to work with a compensated heart defect and then when his heart becomes decompensated, lay that to his work. Furthermore the worker should regulate his life in such a way that he shall remain well. If a man who has been doing a day's work takes a stimulant at its close, when he needs food, he will get sick. Such illness is not, however, due to his work. A girl who has been working all day and who spends her evenings in exciting and hilarious amusements, when she needs rest, cannot blame her occupation for any heart disease or lung trouble that may follow.

It is perhaps not necessary to say anything specifically relating to tuberculosis. Those who are engaged more particularly in discussing the treatment of tuberculosis have published much information available to the public concerning the methods by which that disease is disseminated. The one great source of tuberculous infection is dry human sputum. This sputum need not be very large in amount to infect a fellow employee or to give a factory a bad name among workers. I believe that it is legitimate for an employer to insist that every person who works in his factory shall be examined before he is given employment. On the other hand, I believe that employees have the right to insist that one of their number who has a chronic cough shall be examined for evidence of pulmonary disease, if they are to continue to work with him.

I presume that the healthiest body of workers in the United States is to be found in the army and the navy. When a man applies for enlistment in either of these services he is first subjected to a careful physical examination; not with part of his clothing on, but with all his clothing removed. Work in the army and the navy, so far as the development of disease is concerned, is no more dangerous than work in a steel plant, a brass foundry, or any another industrial plant.

In a discussion on industrial disease held jointly by the American Association for Labor Legislation and the American Medical Association, in Atlantic City, in 1912, the surgeon general of the navy said: "We have been working after occupational diseases in the navy; but entirely on the basis of military efficiency. There is no humanitarian factor in it." Why should not a manufacturer look after the health of his employees entirely on the basis of industrial efficiency? His work would be done better and his employees would lead healthier, happier lives.

I should like to suggest that some corporation interested in the health of its employees, require a certificate of health, based on a careful physical examination, from each individual on its payroll. Then the subsequent medical history of the employees might be studied and the occurrence of diseases among them could be recorded and investigated as to their relation to the work and to the habits of the employees when not working. Some one will want to know what provision will be made under such a scheme for the employment of those men who present certain physical defects when they apply for work. In such a system, it seems to me, patients with heart and lung disease can be given suitable employment, and not set to work at tasks too great for them, as is now very frequently the case. Such an inquiry would be productive of much valuable information concerning the effects of industry on the health of the workers. It would require, however, for the best results, that the physician in charge of such a department should be a man of sound judgment, capable of undertaking original investigation.

457 Park Avenue.

DIABETES MELLITUS.

Treatment with Bacillus Bulgaricus Cultures.

By J. WALLACE BEVERIDGE, M. D.,

New York.

In presenting a new therapeutic measure for the treatment of diabetes, great caution should be maintained toward an optimistic viewpoint until a sufficient number of positive recoveries are noted which would warrant an assertion that such a procedure as that herein recorded is of true value. The results in the 176 cases cited, and observations made by Dr. George F. Klenann and myself in this preliminary report, should in no way be considered as final.

It is necessary to portray a brief outline of the
main etiological factors in this disease, so that we may be enabled to indicate how the conditions causing functional glycosuria are overcome. The pancreas is the gland whose secretion is known to have the most power in breaking down the carbohydrate group, which is readily divided into the polysaccharides, starch, and cellulose, the diysaccharides, maltose, lactose, and saccharose, and the monosaccharides, dextrose, levulose, and galactose. The most important carbohydrate, as a food, is starch, but, as such, is valueless, though easily broken down by the digestive enzymes. The saliva and pancreatic juice contain a diastatic ferment capable of changing the molecular cohesion of starch into maltose as an end product, and in some of the herbivora an enzyme capable of attacking cellulose, which has not been definitely isolated in the human being, has been demonstrated. During digestion the activity of the pancreatic secretion depends mostly upon the acidity in the duodenum and small intestine, this acidity causing a peripheral, local stimulating reflex action on the ganglionic cells scattered throughout the pancreas, while the reflexes of central origin remain inert.

Popielski, Wertheimer, and Le Page demonstrated that when an acid was introduced into the duodenum, pancreatic secretion was excited, and they were able to prove that pancreatic secretion could be induced by the injection of acid into the small intestine, the effect diminishing as the acid neared the lower end of the intestine. The name of the product formed inducing pancreatic activity is known as "secretin." Bayliss and Starling confirmed the results given above and justify the statement that "when the acid gastric juice of digestion reaches the duodenum, the prosecretin manufactured by the epithelial cells is converted into secretin, which is immediately absorbed into the blood stream, then carried to the cells of the pancreas which at once are stimulated to secretory activity." This process, showing the power exerted through the stimulation of acid digestion in producing secretin, so necessary to the normal functioning of the pancreas, has never until now been brought forward as a factor in glycosuria. Hence, one can readily perceive that when chronic conditions arise to change the acidity of the gastric contents, a corresponding response will be noted in the production of secretin. According as an increased acidity or lowered acidity of the gastric chyle is apparent while passing through the duodenum and upper portion of secretion. According as an increased acidity manufactured is either increased or diminished, and, reflexly, the pancreatic secretions will also be increased or diminished. Should this abnormal chemical reaction continue, whereby the pancreas receives inadequate stimulation during digestion, serious chemical and metabolic changes will in time manifest themselves, which may eventually combine and prevent complete carbohydrate metabolism.

The other causes interfering with a normal production of secretin are intestinal putrefaction, ulcer of the duodenum or pylorus, and any lesion involving the mucosa of the duodenum and upper portion of the small intestine.

The liver, next to the pancreas, furnishes the most important etiological factor, but in this paper a complete exposition of its action in digestion is impossible. Only a very brief indication of a few cardinal points will be undertaken. The power of the liver cell to change ammonia into urea is vital. When any abnormal cellular change manifests itself the urea content found in the daily urine is lessened and the ammonia output increased. This fact is observed in all severe cases of diabetes, in anemias, in some types of intestinal nephritis, in toxemias, in hypertrophic and atrophic cirrhosis of the liver, in chronic inflammations of the gall duct, and in malignancy. A continued low urea output is an unfavorable sign in diabetes. Generally, we find that when the liver is unable to normally change ammonia into urea the secretion of the bile is affected, the production is lessened, and the bactericidal action diminished.

The intestinal tract also plays a most important part in carbohydrate metabolism. In more than ninety per cent. of the cases under observation there was intestinal putrefaction, usually traced to chronic constipation, intestinal stasis, or lack of proper bodily care. The normal action of digestion is dependent upon the daily intestinal elimination and nonabsorption of the waste products; otherwise interference with oxidation, as a result of auto-intoxication, will coordinately affect the entire internal secreting glandular system, and, should such a chronic state ensue, cellular changes in the thyroid, pituitary, and pancreas, oftentimes begin. Of course, constipation is the main cause of all intestinal disturbances, and to-day we can be reasonably certain whether a chemical or mechanical derangement is paramount.

The chemical faults may be ascribed primarily to improper food, such as food of poor quality, food badly prepared, or unbalanced food consisting

---

**Fig. 1.**—Transverse colon is adherent to the cecum as result of chronic appendicitis. AC—GC, resolving in acute angulation of hepatic flexure with tesis; stomach is ptosed.
either of carbohydrates or proteids in excess; interference with the chemical activating agents of peristalsis, i. e., bile, etc., and the noxious chemical products of intestinal putrefaction, come under this heading. The mechanical faults are demonstrated by the radiograph, briefly indicated from observations made by Dr. A. J. Quimby, professor of radiography at the New York Polyclinic Medical School, on some 350 patients and upon cases submitted by me, in which the patient's stomach and intestines have been radiographed following a test meal of bismuth. In this series the mechanical defects portrayed were frequently marked, and the data obtained through this accurate determination of the stomach and intestines, have proved most valuable, especially in the prognosis and treatment. The radiographic plates of the stomach, as a rule, show mechanical changes indicating dilatation or perhaps stenosis of the pylorus or duodenum, while in the ascending and transverse colon frequent sharp angulations are seen, probably due to adhesions, and should the accentuation of the hepatic or splenic flexures be well defined, caused by adhesions of sufficient density to deflect the relative position of the intestine, considerable delay in the passage of the semisolid bowel contents will result.

In all conditions of intestinal stasis the sigmoid deserves special study. In infancy the sigmoid is much longer proportionally than in adult life, and Jacobi has frequently pointed this out as one of the dominant mechanical factors in producing constipation. In adults, if the functions of the sigmoid are interfered with by direct pressure or by ad-
one, or both combined, is always necessary for a diabetic state to manifest itself.

THE BACILLUS BULGARICUS.

Much controversy has arisen, since the international employment of the Bacillus bulgaricus culture for intestinal putrefaction, as to whom the credit should belong for first isolating this organism. It seems that Professor Kern, in 1881, first published an article describing the microorganisms found in Russian kefir. At this early period the bacteriological technic was perhaps untrustworthy for accurate information, and judgment should therefore be withheld on the question whether the true Bacillus bulgaricus of to-day was isolated at that time. Beijerineck unquestionably was the first to positively demonstrate the isolation of the Bacillus canadensis, which belongs to the bulgaricus group. Two distinct classes of this organism have been demonstrated, and the first investigators to prove this fact were Rist and Khowry. A true bacillus isolated from the Bulgarian yoghurt by Grigoroff, a member of Professor Massol's laboratory staff, and first described by him as the Bacillus bulgaricus, is the organism now used as a therapeutic agent. A further point of interest is the report by Heinemann and Hefferan that they were able to isolate this bacillus from many sources, asserting they found a bacillus identical to that of the bulgaricus in the human feces, in the feces of cows and horses, also in a great variety of sour and aromatic foods, in the human saliva, in the normal gastric juice, and in the gastric juice when hydrochloric acid is absent in the fermented milk and ordinary sweet milk. Cohendy devised the present media for active growth.

MORPHOLOGY.

The characteristics are similar in all strains. Length, two to fifty; breadth approximately, one. All viable bacilli are Gram positive and are regular in shape, the appearance is that of a straight line with rounded ends; no granules or vacuoles observed. Two strains noted are, A and B. Their culture in whey (Class A) indicates a tendency toward degeneration and involution. In the beginning of incubation, at 37.5° C., the bacilli are uniform in size. In outline all are markedly Gram positive, while in the succeeding stages the irregular, vacuolated, inflated, and ruptured forms of disintegration predominate.

Class B Cultures.—No stemmed nodules are present, small spherical bodies are seen attached to the cell wall. In the case of the stemmed nodule a single bacillus rarely, if ever, extrudes more than one bud, while in the latter instance the bacterium may have a number of these small spheres adherent. Strains of Class A culture grow in the form of a short bacilli arranged in chains. Strains of Class B culture develop to a greater length and exist almost exclusively as single isolated forms. Examined in a hanging drop, no motility is observed. Milk is the natural habitat of the Bacillus bulgaricus and the morphological features which the bacilli manifest in this media should constitute a standard. Early growths show a variable length, the width alone remaining stable. When grown with the addition of yeast and more trivial ferments, the length of this bacillus is inhibited. Very little degeneracy occurs from the bacillus grown in milk media; no vacuoles or nodules observed. No spores were observed. The fact that these bacteria when young

FIG. 4.—Marked ptosis and dilatation of cecum, C; redundant sigmoid, Sg.

FIG. 5.—Adhesions of gastric omentum; gastric stasis due to angulation of duodenum; flac stasis.
and most active exhibit a low degree of vitality would argue against the possibility of spore formation. Nothing to suggest the presence or formation of capsules was noted. All strains readily stained by the usual anilines.

Other Media.—When freshly isolated from their natural symbiotic environment no growth is obtainable on ordinary media. After a year’s solitary cultivation in milk, these bacteria show an increased vitality and adaptation to foreign environment. A feeble growth was obtained on nutrient agar from strain A. The same agar with two per cent. lactose added was barren of growth, while with dextrose, a strong collection of healthy colonies began to grow. In lactose bire enriched with peptone a feeble, though constant, growth ensues; proving that the inhibitory action of the bile on the Bacillus bulgaricus in the small intestine is absent. No gas is formed while the bacillus is grown in this bile medium. No difference as to growth was seen under aerobic or anaerobic conditions. Gregoroff states that the Bacillus bulgaricus attacks mannite, saccharose, maltose, and lactose, but not rhamnose, dulcite, or sorbite. Cohendy observed the active fermentation of lactose, maltose, saccharose, levulose and particularly dextrose. Bertrand and Duchaecck state that the “carbohydrates” fermented by the Bacillus bulgaricus are dextrose, mannose, galactose, saccharose, levulose, and lactose, while arabinose, zylose, and sorbose are not changed.

Enzymes.—The addition of calcium carbonate, calcium chloride and zinc chloride in excess of the amount required to neutralize the acid production, to prevent the coagulation of milk, failed. This might argue for the presence of an enzyme.

Acids Produced.—From a five day culture Bertrand and Weissweiller isolated lactic acid by means of the zinc salts and conclude that the acid formed was a mixture of the levo and dextro modifications, with a predominance of the latter. Besides lactic acid, acetic, formic and succinic acids have been demonstrated by Bertrand, Weissweiller and Duchaecck. Heinemann finds that the volatile acids constitute 5.8 per cent. to 6.1 per cent. of the total acidity.

Pathogenicity.—The Bacillus bulgaricus is non-pathogenic to man or the usual laboratory animals. No untoward effects have been observed following the ingestion of large amounts of this culture.

The cultures of the Bacillus bulgaricus employed by men are grown upon a modified Cohnedh medium, which from time to time I have had examined in reference to the purity and viability of the organism by the Gram positive method, the average count being 285,000,000+ positive per cubic centimetre. with an acid activity of from one to 3.6 per cent. in twenty-four hours upon sweet milk.

In the preceding description of the Bacillus bulgaricus its action upon sugar, with the formation of lactic acid, is indicated. In diabetes the carbohydrate radicle is attacked in the intestinal tract by this bacillus and converted into lactic acid. The necessity for starch as a food is well known, and if digestion is unable to break down the molecules of starch, in glycosurias it is harmful. But by this action of the Bacillus bulgaricus this much needed carbohydrate may be taken with little, if any, excess of sugar appearing in the urine. This chemical reaction is of great importance when the normal combustion of sugar in the alimentary tract is at fault, and if we are able to continue the use of an active culture aid is given the pancreas and liver to complete the carbohydrate digestion. When the pancreas receives weak stimulation by the lack of a normal quantity of secretin forming, as a result of a low gastric acidity, the potency of this bacillus to make lactic acid is of value in further stimulating the duodenum and upper portion of the small intestine. The antiseptic and corrective power of the bacillus, by overcoming auto-intoxication and all conditions of intestinal putrefaction is very marked. Its distinct action in attacking the hosts of intestinal flora and the chemical action of the lactic acid upon the waste products such as indol, skatol, zanthin, and hyperzanthin, may possess, according to Professor Belonowsky, a still greater cleansing influence by an active product created during the proliferation of the bacillus. He positively asserts that this substance continues exercising a protective influence against reabsorption. The action of this culture is never manifested unless the microorganisms are viable when administered.

1. Last three urine analyses made at French Hospital; sugar in each report, trace only.

Amount.2

CASE I. Mrs. A. M., Portland, aged forty years, married, five children. Thin, weight 120 pounds, slightly neurotic: mentality low. Slept poorly; arose from five to seven times to void urine. Appetite poor. Severe chronic constipation. Polyuria; painful menses; slight vaginal discharge; pruritus. Heart: normal; liver readily palpable; stomach, no dilatation. Complained of severe shooting pains in legs, burning and itching of vulva, headache, excessive thirst, and constant desire to micturate; eyesight impaired; loss of appetite and inability to sleep. Treatment: Patient difficult to control, going back home during September and October; then returned with 8+ per cent. sugar. Improved somewhat symptomatically, but a severe uncontrolled pruritus developed. Finally, took her to the French Hospital and kept her under close observation. A trace of sugar present upon her discharge. Weight 125 pounds. Modified diet: from four to six tubes of culture used daily. Sodium bicarbonate, pancreatic ferments, and salol. Prognosis, excellent; no pruritus. Discharged April 15th, without symptoms.
CASE II. Mr. A. W. K., contractor, aged twenty-nine years, married. Stout, weight 167½ pounds; very nervous; mentality medium. Slept well; appetite good; constipated chronically. Urine amount, from seventy to eighty ounces; arose once at night. Habits moderate.

Family history; mother had diabetes; report as to father negative. Previous history; diseases of childhood; diabetic state one year and a half. Heart, normal; liver, not enlarged; stomach, slightly dilated. Pulse 100, blood pressure 70. October 20th. Pulse 100, blood pressure 48 mm. Hg; complained of severe headaches; constipation; malaise; considerable loss of weight, from 215 pounds to 167½ pounds; indigestion. Physical condition good; pain voided in twenty-four hours. forty-two ounces; no pains noted. On normal diet; discharged.

Case IV. Dr. F. P. K., Brooklyn, aged forty-nine years, married. First seen September 13, 1912. Stout, pendulous abdomen; weight 179½ pounds; slight clubbing; thighs slightly high. Slept poorly; arose from three to four times each night to void urine; polyuria, 105 ounces daily. Appetite good; markedly constipated; habits moderate; appetite inclined to overeat; nutrition excellent. Treatment: Three tubes of culture daily; pancreatic ferments; sodium bicarbonate; modified diet. To-day, regular diet, one tube every other day. No symptoms; weighed 176½ pounds. Prognosis, positive recovery; discharged.

CASE III. Mr. H. B., aged thirty-eight years, married. First seen July 17, 1912. Stout, pendulous abdomen; men-

Physical condition good; skin moist; bodily nutrition excellent; tongue heavily coated. Pulse 91, blood pressure 165. Complains of severe thirst, considerable loss of weight, polyuria, excessive micturition, drowsiness, loss of ambition, disinclination to work, cramps in calves of legs, and great weakness. Treatment: Modified diet; from four to six tubes culture daily; so-
dium bicarbonate, five grains every three hours. Pancreatic ferments. This had been continued with slight variation; instead of sodium bicarbonate, calcium chloride was occasionally administered. To-day patient's condition is practically normal. Diet regular; no symptoms are present, sleeps all night; voids only from forty-five to fifty-five ounces of urine daily; bowels regular; weight 188½ pounds; is able to attend to all his professional duties without any inconvenience. Result, brilliant. Prognosis unquestioned toward recovery.

Case V. Mr. F. N., aged forty-four years, married. Weight 166½ pounds; stout; slightly neurotic; mentality high; slept poorly; appetite good; chronic constipation; some polyuria; habits moderate. Heart, presystolic murmur at apex, size normal; liver, greatly hypertrophied; stomach, dilated; lungs, chronic bronchitis; involvement of right apex; sputum examined; tubercle bacilli present. Pulse 92, blood pressure 140. Family history; mother died from chronic nephritis, acute exacerbation; father's history negative. Rheumatic attacks during last five years; first noticed present condition three years ago. Complained of excessive thirst, great weakness, cramps in legs, frequent micturition, severe headaches, and indigestion. Treatment: Patient inclined every few weeks to drink to excess. Acidosis present; day following given from four to six tubes culture daily, with ferments and sodium bicarbonate. Glicosuria much improved and diabetic symptoms absent upon last examination, but tuberculous process in lung necessitated sending patient away; final outcome in doubt. Prognosis poor; weight 157 pounds.

(To be concluded.)

FURTHER NOTES ON PROSTITUTION IN JAPAN.

Abolition of the Slavery System; Early History of the Yoshiwara; Illicit Prostitution; Medical Inspection and Statistics; Jurisprudence.

By DOUGLAS C. McMURTRIE, New York.

I.

The abolition of the absolute slavery of prostitutes in Japan took place in 1872, and was due more to chance than to any conscious demand on the part of the people. In fact, the indirect effect of foreign influence was the most potent factor. A ship loaded with slaves bought in China stopped at Yokohama harbor on account of a storm at dusk, and while it was at anchor one of the slaves jumped overboard and swam to an English warship which was lying close at hand. The captain of the warship reported the matter to the authorities and requested that the slaves be released, as the dealing in human flesh was contrary to the standards and principles of civilized countries. As at the time the Japanese government considered it most essential to maintain cordial relations with the civilized nations, the ship was detained and the captain was ordered to release the cargo of slaves. The captain, however, filed a protest, and when the matter came up for decision before a special court, he presented a copy of a contract or bill of sale of a girl then serving as a prostitute in the city of Yokohama. He claimed that he could not be interfered with because the sale of human beings was permitted by the Japanese authorities themselves. The court was much perplexed by this development and postponed the case. When the matter came up for final hearing the court ruled that traffic in human beings was not legal in Japan, and that the reason such a traffic existed was because no one had appealed to the courts to prohibit it. In the case in point the law had been invoked, and the court maintained that it had the power to order the release of the slave cargo. The order was issued and executed, and the enslaved Chinese were sent back to China. Soon after, an order emanated from what then corresponded to the Department of Home Affairs, emancipating all women held under contract for immoral purposes. An order from the Judicial Department followed, protecting the released women by enjoining the courts from entertaining suits against them for debts due their masters.

The actions already described abolished the legal status of the practical enslavement of prostitutes. The present system was established, the term for licensed house being changed to kushizashiki or "parlor renting." Persons desiring to conduct brothels were required to locate in the section designated by the authorities, and on receiving the necessary permit, they were expected to rent their rooms to women licensed by the police to ply their trade as prostitutes. Actually, however, the system has worked out far differently, and the original plan is adhered to only nominally. By making an advance payment or loan the keepers of the houses executed contracts with the prostitutes securing their services for a specified term. At first this latter was generally set as three years. By this means most of the former inmates of the houses were released.

II.

In a previous article I have referred to the petition of 1612 of the brothel keepers of Yeddo (which was the old name for Tokyo) for the establishment of a special segregated quarter. The reasons given in this petition are of considerable interest in tracing the history of the yoshiwara. After calling attention to the fact that such quarters already existed in other localities, it goes on to state that "houses of ill fame abound in every part of the city, being scattered hither and thither in all directions. This, for numerous reasons, is detrimental to public welfare and morality." The reasons given are as follows:

1. As matters stand at present when a person visits a brothel, he may hire and disport himself with yujo to his heart's content, and give himself up to pleasure and licentiousness to the extent of being unable to discriminate as to his position and means and the neglect of his occupation or business. He may frequent a brothel for days, giving himself up to lust and revel, but so long as his money holds out the keeper of the house will continue to entertain him as a guest. As a natural consequence, this leads to the neglect of duty toward masters, defalcations, theft, etc.; even then the keepers of the brothels will allow the guilty guests to remain in their houses as long as their money lasts. If brothels were all collected into one place a check would be put to these evils, as, by...
means of investigation and inquiry, a longer stay than twenty-four hours could be prohibited and such prohibition enforced.

2. Although it is forbidden by law to kidnap children, yet, even in this city the practice of kidnaping female children and enticing girls away from their homes under false pretenses, is being resorted to by certain vicious and unprincipled rascals. It is a positive fact that some evil minded persons make it a regular profession to take in the daughters of poor people under the pretext of adopting them as their own children, but when the girls grow up they are sent out to service as concubines or prostitutes, and in this manner the individuals who have adopted them reap a golden harvest. Perhaps it is this class of abandoned rascals that even dare to kidnap other people's children. It is said to be a fact that there are brothel keepers who engage women, knowing perfectly well that they are the adopted children of the parties who wish to sell the girls into prostitution. If the prostitute houses were all collected into one place, strict inquiries would be made as to the matter of kidnaping and as to the engagement of adopted children, and should any cases occur in which such reprehensible acts were attempted, information would be immediately given to the authorities.

3. Although the condition of the country is peaceful, yet it is not long since the subjugation of Mino province was accomplished, and consequently it may be that there are many romin prowling about seeking for an opportunity to work mischief. These ruffians have, of course, no fixed place of abode and simply drift hither and thither; so it is impossible to ascertain their whereabouts in the absence of properly instituted inquiries, even although they may be staying in houses of ill fame for a considerable number of days. If the authorities grant this petition and permit the concentration of the existing brothels in one regular place, the brothel keepers will pay special attention to this matter, and will cause searching inquiries to be made about persons who may be found loaing in the prostitute quarters, and should they discover any suspicious characters they will not fail to report the same to the authorities forthwith.

It will be deemed a great favor if the august authorities will grant this petition in the fullness of their magnanimous mercy. Another factor bearing on the segregation system was the attitude of the army authorities who favored it. It is related by Maget that, about 1815, Yorimoto organized the first imperial standing army, and the divisions were stationed at various points, notable at Kamakura, Osaka, Kyoto, and Nagasaki. In order to protect the public from annoyance, Yorimoto segregated and regulated prostitution in the vicinity of the garrisons.

The inmates of the Japanese houses are known by various terms: Orian, or wife for an hour, is the least derogatory; shogi, or prostitute, the common appellation; joro, or harlot, implying the shame of her calling; and yufuo, or daughter of joy, corresponding to the French idiom fille de joie.

In addition to the citations already made it may be mentioned that general descriptions of the yoshiwara and its history have been given by Hintze and Matignon.

III.

Legalizing prostitution in Japan has not settled the question, and there has always been a large amount of clandestine or illicit prostitution. In Tokyo in 1722 the latter had grown to such considerable proportions that a proclamation was issued by the governor of the city. The text of this was as follows:

Whereas secret prostitution has been prohibited in the wards of this city, and whereas it appears that the practice has been carried on in an audacious manner, it is hereby ordered that henceforth secret prostitutes shall be treated as follows:

The person harboring secret prostitutes will be ordered to yield up to the government his ground lot, furniture, house, and godown, and the woman offending shall herself have her furniture seized, and for the space of 100 days shall be manacled with irons and committed into the custody of the responsible parties of her ward, an officer being detailed off to visit the house every other day to inspect the seal on her manacles.

2. The owner of grounds and houses in which secret prostitution takes place shall be held in the same penalties, viz., although he is not personally engaged in the practice, but only represented by a caretaker. The caretaker shall have all his furniture seized, and shall be manacled for a period of 100 days, during which period he will be committed into the custody of the responsible parties in his ward, and every other day the bonds shall be examined and the seals inspected.

Three days after this date the appointed officials and yoshiwara authorities will proceed to search for persons carrying on illicit prostitution, and if those persons are apprehended they will be dealt with as stated above.

Persons harboring offenders may be punished with bannishment or death, and, moreover, the members of the ward who are responsible for the parties may be likewise punished in accordance with the foregoing. Now, therefore, take notice, and let this be published throughout the city.

An additional order was issued in 1876, as follows:

Persons practising secret prostitution and the keepers of secret houses used for that purpose shall be punished as follows: Principal or accessory: First offense—Fine not exceeding ten yen or two and one half months imprisonment. Second offense—Fine not exceeding twenty yen or five months' imprisonment. Keeper of the house: First offense—Fine not exceeding fifteen yen or three months' imprisonment. Second offense—Fine not exceeding thirty yen or six months' imprisonment.

IV.

Segregation of prostitution was of early origin in Japan, but medical inspection was not inaugurated until later. Its establishment was largely the result of European influence. A memorial asking for the abolition of licensed prostitution tells of the English Contagious Diseases Acts, and then goes on to say that with the view of protecting the soldiers and sailors then in Japan or going there, a hospital for the treatment and examination of pros-

stitutes was established in Yokohama in 1867. This was at the suggestion of naval surgeon Doctor Newton. In 1872, under the supervision of an English army surgeon, Doctor Hill, the system was extended to Tokyo and also to the open ports of Kobe and Nagasaki. Later, in 1876, the government established the system in nearly all the cities and prefectures of the empire.

The regulations of the central government require that all prostitutes must be registered and examined periodically. The details of management are, however, left to the prefectural offices. The local police departments of a prefecture prescribe a code which is approved by the governor and put into force by his order. There is also another set of regulations made by the keepers of the houses for their own guidance and protection. Such regulations must be submitted to the police authorities, and when approved by them are binding on both keepers and inmates.

When a prefecture desires to license prostitution the governor makes application to the Department of Home Affairs. Upon the granting of permission by this authority the prefectural assembly must appropriate the funds necessary for the system of regulations. The prefectural regulations must be consistent with the general code promulgated by the Department of Home Affairs. This code came into force in 1900, previous to that time the Tokyo city regulations being taken as a guide.

A translation of the code of regulations issued by the Department of Home Affairs in 1900 is here given.

Regulations for the Control of Prostitutes. Department of Home Affairs Order No. 44. Issued October 2, 1900.

1. Women under eighteen years of age shall not be allowed to become prostitutes.

II. Only those registered as prostitutes shall be allowed to carry on the business of prostitution. Prostitutes' registers shall be kept in the police stations that have charge of the districts in which prostitutes reside. Those registered shall be subject to police supervision.

III. Those who wish to become prostitutes shall make application in person to the police station and shall present the following items in writing: 1. Reasons for becoming a prostitute. 2. Age. 3. Written consent of nearest relative in applicant's home. Where there is no near relative, consent of the head of the family in which the applicant is domiciled; where there is no one to give consent, explain reason. 4. In the case of minors, in addition to the foregoing, written consent of real father, consent of mother; where there is neither father nor mother, consent of real grandfather; where there is no grandfather, consent of real grandmother. 5. Place of business. 6. Domicile after being registered. 7. Present trade. In case of being supported by others, give particulars. 8. Whether applicant has ever served as a prostitute before. If so, give date of beginning and cessation of business, place of business while a prostitute and reason for cessation of business. 9. In addition, give all particulars required by prefectural regulations. Application must be accompanied by a copy of the family registry, and attested consent of persons mentioned in Articles 3 and 4.

All applicants must pass a physical examination before being enrolled.

IV. Prostitutes who have been ordered to cease business shall be dropped from the prostitutes' register. In all other cases erasure from the official register shall take place only upon application of prostitutes in person; provided that in the case of minors the persons named in Section III. Articles 3 and 4 may make the application for erasure.

V. Requests for erasure from the prostitutes' register may be either written or oral. Such requests shall not be entertained by the police unless made in person at the police station. Exceptions shall be made, however, in the case of requests sent by mail or messenger when the police believe there are reasons that the applicant cannot appear in person. As soon as requests for erasure have been accepted by the police the application of the prostitute making the request must be stricken from the register.

VI. No person whatsoever shall be allowed to interfere with a request for erasure from the official register.

VII. Prostitutes shall not reside outside of the districts designated by prefectural regulations. They shall not go out of the brothels except by police permission, unless it is in obedience to official order or to visit the police station, provided, however, that exceptions shall be made where prefectural regulations specify certain limits within which they may go out.

VIII. Prostitution shall be carried on only in brothels which have official permits.

IX. Prostitutes shall submit to the physical inspection provided for in the prefectural regulations.

X. When the physicians or hospital authorities appointed by the police decide that a prostitute is suffering from contagious diseases or from any complaint that renders her unfit to receive guests, she shall cease business and not be permitted to resume it until she has recovered and passed a physical examination.

XI. The police authorities may refuse to register applicants for prostitution. The prefectural authorities may suspend or prohibit prostitutes' business.

XII. No person whatever shall obstruct the liberty of prostitutes in regard to correspondence, privilege of meeting people, reading literature, purchase and possession of necessary articles, or in any way interfere with their liberty or business.

XIII. Persons committing the following named offenses shall be liable to a fine of twenty-five yen or imprisonment for twenty-five days: 1. Making false statements to secure the registry of prostitutes. 2. Violating Sections VI, VIII, IX, and XII. 3. Violating Section VII and causing prostitutes to ply their trade outside of licensed brothels. 4. Violating Section X and compelling diseased prostitutes to resume work before passing official inspection. 5. Violating suspension order of Section XI and compelling prostitutes who have had their business suspended to ply their trade. 6. Causing the registry or erasure of registry of prostitutes against their will.

XIV. In addition to these regulations such other matters as may be deemed necessary shall be determined by prefectural regulations.

XV. Prostitutes who are already serving when these regulations go into effect shall be regarded as having been officially enrolled.

The physical inspection referred to in Section IX is performed by designated physicians and occurs on the average of once every week. A special police officer enforces the examination when necessary. The inspection whenever possible is arranged for a day following the weekly holiday. Such prostitutes as are found to be suffering from venereal disease are sent to a special segregated hospital. In places where the number of prostitutes is small the examination is conducted by some physician under police permit, and the girls are detained in a part of some local hospital. Cases of ordinary illness may be treated either at the home of the keeper or in ordinary hospitals, but in each case police permission must be secured. The length of detention in the segregated hospital varies with the nature of the complaint and the strictness of the physician in charge.

In 1899 the chief medical officer of the Japanese navy, Dr. Tatsurabo Yabé, alarmed at the increase of venereal disease, issued a plea for more stringent supervision and inspection of prostitution in the
seaports. He presented facts as follows: In 1896 in the whole country there were 43,570 registered prostitutes, and the number of medical examinations made during the year was 2,030,267. There were detected 8,856 cases of syphilis and 61,504 cases of gonorrhea. Of course, a great number of the latter were relapses or reinfections. In Tokyo, the number of cases of venereal disease in proportion to the total examinations made was seven in 100. These figures, according to Doctor Yabe, show the necessity for rigid sanitary supervision. That venereal disease is more prevalent among sailors than among landmen is, he states, due in part to the frequency of clandestine prostitution in seaport towns and in part to the special character of a sailor's life. In the Japanese navy a sailor suffering from venereal disease is forbidden shore leave, so that he cannot transmit infection to others.

In 1896, during the year, 157,5 men in 1,000 in the navy contracted venereal disease. The total days of disability from all causes in the year was 196,823, and of these 85,867, or over forty per cent, of the total, were due to venereal causes.

In Japan the system of prostitution is entrenched more firmly than in almost any other country. An anonymous English author quoted by Buschan places the number of houses of prostitution throughout the empire at 20,000 and the number of women employed in them at between 400,000 and 500,000. Buschan also notes with surprise that the houses are often the handsomest in a city, that they are located in proximity to temples, and that they have almost the status of public institutions.

The figures just named are probably exaggerated to a large extent. The official figures for the year 1896 show the average number of prostitutes in Japan to have been 43,570, but this was only the number who were registered and subject to actual medical inspection. The actual number of women engaged in prostitution was, of course, much larger. Murphy quotes figures gathered by him from the various prefectural offices. The number in 1896 (39,068) is but slightly lower than the one just given, and this difference might be expected. The other figures obtained by the same method are as follows:

<table>

In addition to the articles already referred to there have been other medical studies by Japanese physicians. Among the latter may be mentioned Kurimoto, Matsui, and Tanaka.

Japanese jurisprudence has, following the example set by other countries, taken little notice of prostitution as possible. Earlier in the present article has been described the incident which led to the prohibition of the absolute slavery of prostitutes. But through various devices the system lapsed back almost into its former state, and the status of the prostitutes as far as freedom was concerned. Girls who ran away from the brothels were searched for diligently by the police and if found were returned and kept there. It thus became practically impossible for a girl to abandon an immoral life, even should she so desire. In view of this state of affairs, some American missionaries took an interest in the situation and endeavored, though unsuccessfully, to induce the crown procurator, or attorney general, to take the part of such women as wished to get away from a life of shame. Failing in this, an effort was made to get a test case before the courts. This proved impossible, however, owing to the fact that police rules are issued by the executive authorities, and their validity is not subject to review by the courts. The only way to secure the appeal of a regulation is to petition the department which has issued it. This was manifestly not possible. The law provided that prostitutes could cease their business provided they made a report to this effect signed by the keeper of the brothel. Naturally, as long as the girl was of value this signature was impossible to obtain. The missionaries then sought to secure the freedom of a prostitute desiring to cease her trade on the following grounds: 1. The contracts that bind prostitutes against their will must be declared null and void, because of the immoral purpose involved; 2, even though the financial part of the contract be considered as binding, still a person cannot be deprived of liberty because of debt, for that would constitute slavery; 3, the girl having attained adult age, could not be bound by a contract made by her father while she was a minor, especially when such a contract had the effect of depriving her of her liberty. This case and several subsequent ones were delayed and hampered in every possible way. The courts and police were in constant conflict, though no one seemed to be much disturbed by the situation. For several years various cases dragged along in the courts and injunctions which were issued from time to time were impossible of enforcement. It was not until public opinion was aroused, largely through the
EXOPHTHALMIC GOITRE.

Report of a Case.

By S. J. Essenson, M. D.,
New York.

Every physician has seen cases of exophthalmic goitre, but the symptoms are so numerous and complicated that each and every case is a study by itself. The excuse for reporting my case is the interest of the course of the disease and the various predominating symptoms due to thyroidism:

Mr. W. W., about forty-six years of age, born in Russia; had been in this country about sixteen years, a farmer by profession, and was married to a woman of the same occupation. These two children were born from the union. The elder one was a girl, mentally defective and having heart disease; the younger, a boy, had chronic bronchitis. The previous and family history of the patient was of no interest; there was no hies, no tuberculosis, nor any nervous affection of organic type, but the members of the family I knew were all neurasthenics, and their nervous trouble of a functional character. He had never been addicted to alcoholic beverages, but, like most Russians, was a great tea and coffee drinker. His goitre affection appeared fourteen years ago; for the last two years at least had been almost constantly under medical care. For several months in succession he was an inmate of a downtown hospital. About six weeks ago his wife brought him home. I saw him for the first time weak; complained of pain in chest and abdomen; coughed much and the expectoration was bloody; suffered headache and dryness of the mouth. He had no desire for food and had a diarrhoea; any food, milk, or medicine ingested seemed half an hour later voided very little urine; the first twenty-four hours of my acquaintance with the patient, he passed about eighteen ounces. Ureanalysis disclosed only a trace of albumin and some phosphates. On physical examination I could but diagnose a condition;

On inspection, extreme emaciation; very marked exophthalmus; the lids did not cover the eyes when closed, especially the upper lids, but vision was apparently unimpaired, even though there was a moderate conjunctival inflammation. The thyroid gland was symmetrically bilateral enlarged, but the swelling was not very prominent. The tongue was coated. The apex beat of the heart could be seen at the seventh interspace, rather to the right of the sternum. The respiration had a dyspnoic character and was associated with a systolic murmur heard even at the ensiform appendix. In the pulmonary region the respiratory murmur was very feeble, and bronchovesicular in quality at the superior and inferior scapular regions. Crackling rales were heard on both sides with inspiration, resulting crepitation of the intercostal spaces. The urine, from which he was brought (where he had been an inmate for several months) told me that such attacks of pulmonary congestion with threatening edema had been noticed several times. It had been the custom before I took charge to all of him to sit up or walk again 1/24, 1/24 every two or three hours. In three days he was able to retain fermented milk and in about a week his condition was again satisfactory. On the advice of his former physician, who had known him for the last fourteen years was given small doses of antithyroid preparation, and then the pulse fell to 60, and was of a better quality than before. The nurse reported to me once that his pulse during the night was 30. I then stopped the digitalis for a time, but the intermitency became worse than ever, so that I would go to sleep suddenly, and his pulse fall to 50 or 40 and become very feeble. This was clearly a sign of dissociation of the auriculoventricular junction, either through the hyperthyroidism affecting the bundle of His, or the vagus entering the interventricular branch to the family that the end might be expected at any time. In a few days, however, he regained some strength. The last time I saw him alive he was cheerful and the family hopeful. They did not believe my prognosis correct; but he died during the night, probably in consequence of a heart block.

The greatest interest in this case attaches to the condition of the heart, which was produced in all probability by the oversecretion of the enlarged thyroid. The latter did not effect the nervous system very much. The question in such a case is If the thyroid had been removed by operation or ligature of the thyroid artery been performed, could the patient have been saved?

20 West 110th Street.

TREATMENT OF BLEPHARITIS.—Wecker, in Paris Medical for January 25, 1913, is credited with the following ointment for use in these cases:

B Hydrargyri oxidi rubri ... gr. vii ss. (0.5 grammes)
Liquoris plumbi subacetatis ... gr. bxxv (5 grammes)
Olii amygdae expressi ... Siijs (50 grammes)
Petroli ... 200 grammes
Sig.: Rub gently on the lid margins, once daily.
ANTERIOR POLIOMYELITIS; INFANTILE SPINAL PARALYSIS; POLIOENCEPHALOMYELITIS; ACUTE CENTRAL INFECTIOUS PARALYSIS.

Physical Therapeutics.

By CHARLES M. HAZEN, M.D., Richmond, Va.,
Professor of Physiology, Medical College of Virginia; Department of Physical Therapeutics, Memorial Hospital.

A disease causing deformity and death, occurring sporadically and in epidemics, having an acute stage, but mostly known by its paralytic aftereffects; the result of a specific infection; localized chiefly in the central nervous system, although other organs are involved. The toxemia affects parenchyma of heart, liver, kidneys, spleen, and lymphoid tissues (Robertson and Chesley). Infectious material is not found in liver, kidneys, spleen, bone marrow (Flexner). Bronchopneumonic areas occur (Sachs). The statement made above is not a definition, but calls attention to prominent features of the subject.

The names given as a heading are attempts to cover the pathological and symptomatic range of the disease. Anterior poliomyelitis is the term which will probably be retained, as it points out the chief, but not all the pathology (destruction of cells in anterior spinal gray matter) of the average case. The second name is faulty because infantile patients are few in proportion, the bulk of cases including ages up to twelve or thirteen years, and patients being sometimes far advanced, one sixty-six years old (almost old enough for second childhood). The third name is wider in its range, recognizing that the pathology extends "from the cortex to the sacrum." In fact, since the nasal mucous membrane is proved to be the chief atrium of the disease and this communicates, by means of the lymphatic channels which accompany the short olfactory nerves, with the cerebrospinal fluid at that end of the nerve axis, it is difficult to understand how any part of the central nervous system can escape infection. Variations of this name occur. Holt proposed to call it epidemic myeloencephalitis. The last name, acute central infectious paralysis, is a conglomeration which perhaps covers the most ground and is sufficiently definite. We may add that the extent of the central involvement is shown by many cases reported, such as those by Medin from Norway and Sweden, of cerebral spastic paralysis due to encephalitis with destruction of cortical cells. Clarke reports epilepsy resulting in another case. It is likely, indeed, that we see patients with similar conditions more often than is suspected. We ought also, since the posterior cord is affected, to expect, besides motor symptoms, pain, hyperesthesia and ataxia. In fact, such a disturbance of the sensory part of the reflex arc should be important in its effect upon tone, nutrition, and function. Degenerate cells have been noted also in Clarke's column (Strauss). Other results, not usually observed, but easily understood from the widespread pathology, are spinal accessory paralysis, atrophic paralysis of the head and trunk muscles, throat, face, and eyes (Starr), larynx (Tetra), and deglutition, edema of the floor of fourth ventricle and Sylvian aqueduct, and death resulting usually from respiratory paralysis (as occurred in one of my cases).

The varieties of the disease may be considered both from the locality of the lesion and from the symptoms. Four years ago Wickman proposed to distinguish them as follows:

1. Spinal paralysis (anterior poliomyelitis).
2. Progressive paralysis, usually ascending, Landry's.
3. Pontine polioencephalitis.
4. Acute encephalitis, giving spastic monoplegia or hemiplegia.
5. Ataxic form.
6. Polyneuritic, or multiple neuritic.
7. Meningitic.
8. Abortive (with no paralysis resulting).

Other terms suggested are bulbar poliomyelitis (same as pontine encephalitis), the classical, or gastrointestinal type (sixty-seven per cent of all cases in California) (Gundrum); cerebral and unclassified are suggested by McClanahan, who has chronicled the Nebraska epidemic. Cerebral is the same as encephalitis; there would be some doubt about a special ataxic form, and a question whether the polyneuritic exists at all, the pain and tenderness in these cases being due to posterior cord involvement.

The stages of the disease may be roughly outlined, although no agreement as to their exact division has been arrived at. Incubation in inoculated animals is from two days to five weeks (Flexner) and in the human two weeks (McClanahan; another statement from the Nebraska epidemic is from five to thirteen days). Laborde divides the further progress of the disease into initial (acute) stage, not over one week; stationary, from one to four weeks; regressive, from one to six months; chronic, after spontaneous recovery has ceased.

The question of the infectious period is important; and while this has been considered to be about the same as the acute period, it is better to hold this sub judice from the standpoint of prophylaxis and treatment. The virus is associated externally chiefly with nose and pharynx, and the secretion of these parts may be scattered as spray or dust (vireulence not destroyed by drying or ordinary temperatures), or swallowed and pass through the digestive canal, or carried on the feet of the domestic fly, or transmitted by the bite of the stable fly or the bed bug (no other insect being under suspicion). We should therefore quarantine the patient from the moment of exposure to, at earliest, sometime after the fever has left. Also, Landsteiner and Popper have proved that there are human passive carriers, and we must regard anyone with suspicion who has come in contact with the disease.

The etiology of this disease embraces climate only so far as wetness or dryness, cold or heat, may influence the vitality of the individual, or lead to infection from overcrowding and bad air in cold weather. Overwork and fatigue in some cases is a factor. A neuropathic heredity is distinctly causative. The early age of most patients may be explained by accompanying weakness, although, be-

*Read before the Richmond Academy of Medicine, March 11, 1913.
sides, there may also be favorable lymphatic conditions in childhood; (central canal of cord is said to be open in childhood and this perhaps favors ascending type—Kramer). Frost, of the Marine Hospital Service, calls attention to possible individual susceptibility, and remarks that only a small proportion of those exposed contract the disease; that males are in excess, except in earliest years, and while children more susceptible than negroes. Weakened condition from other contagions may predispose, and tonsillitis, measles, and other diseases have been occasionally seen in patients with poliomyelitis. Malaria and other severe cachexias would be favorable.

The symptoms are those of severe constitutional infection, fever, headache, convulsions, vomiting, diarrhea (or constipation), sweating, etc., of more or less severity. There is a good deal of pain and tenderness; while fever disappears, patient is found to be paralyzed, nerves showing reaction of degeneration; atrophy and deformity following.

Treatment should be considered first as to prophylaxis. Public, domestic, and personal hygiene are of first importance. Under the latter comes the toilet of the mouth, to which should be added the nose and throat. The routine use of suitable nonirritating antiseptic gurgles and sprays or douches and the preservation of these parts should be carefully attended to. Menthol has been shown to be effective against the virus, and children should be taught to use menthol tablets or confections once or twice a day.

The indications in the acute stage are those of any infection, as to elimination, support of patient, control of symptoms. (Hexamethylenamine is no doubt of value. Epinephrin may perhaps have a place in reducing local congestion.) Physical therapeutic methods at this stage are such as apply to similar conditions in other diseases. They should, however, be more actively applied. Kerr, of New York, who furnished Flexner with his first material for successful inoculations, proved the value of the hot pack and the use of hot drinks to favor elimination; also the hot pack tends to relieve central congestion. Control of vomiting and other severe symptoms is favored, and likewise the abortion of the disease. A hot enema, followed by castor oil, should be given. Porter suggests that subcutaneous salt solution might be of use during this period. While using these methods vigorously, especially at the beginning, the strength and repose of the patient should be considered. Quiet and a dark room, a single attendant, are in order. It is suggested that the patient's position should be changed occasionally and that he should not lie on the back. Plaster supports applied in slight lordeosis have been used. Cold applications may be made over the spine, particularly the lumbar region. These active measures are of most value in the first twelve hours, during which no food is given, and thereafter the diet is to be fluid. The keynote to treatment, subsequent to the first twenty-four hours, should be rest, both motor and sensory. It is absolutely contraindicated at this time to begin massage or electricity. The use of strychnine should be condemned unless vitality of patient demands it, and its subsequent use in the chronic stage, except for short periods, is of doubtful value. Morse says, "Rest, not stimulation. Results in New York epidemic show futility of too early and energetic use of massage, electricity, and forced movements."

As the patient overcomes the acute symptoms and fever has ceased and paralysis appears, the physical therapeutical programme should be enlarged. A very important consideration is to support the weakened muscular and joint structures, and pillows, cradles, and splints are to be used. If the muscles are left unsupported, stretching by gravity and nonparalyzed opponents will greatly increase atrophy and paralysis. This should be borne in mind during the whole subsequent course; prosthetic and surgical treatment must favor "the position of maximum relaxation" (Silver). Massage should be gentle and not too prolonged; fatigue must not be produced. Passive motion by an experienced operator is of great value, Mechanical vibration is a home method of value; apparatus can be installed and relatives taught to apply it. Another method of home treatment which will greatly assist is hot and cold water once a day; the limb is steamed with hot cloths for four or five minutes and then cold water for an equal period is poured or rubbed over it. Circulation and reflex action are thus stimulated.

Properly chosen electricity is of great value. The use of faradism is fraught with danger, unless well understood; it is like strychnine, overstimulating. The object of electrical treatment is to improve the life of muscle and nerve, its vegetative function, nutrition, and metabolism; this can be done without stimulating the nerve to manufacture energy or the muscle to contract. The current of choice in my opinion and experience is that derived from the static machine, the bipolar continuous first, and later the bipolar continuous. The patient can take the static current as soon as well enough to be in a roller chair, for a short period, five minutes at first—remembering that fatigue may be produced by sitting up and being moved about too much. In case the static cannot be had, the next preference is the galvanic. A third choice is the unipolar high frequency vacuum tube current; this has some of the properties of the bipolar currents (static and galvanic) and can be regulated so as not to be too stimulating. Electricity and massage should alternate.

The majority of cases are seen after the chronic condition has begun. The orthopedic surgeon has as a rule been consulted. Physical therapeutics are now of the utmost value, it being recognized that "preliminary treatment must be instituted to determine the degree and extent of the paralysis and to put the part in the most favorable condition." Subsequent prosthetic and surgical treatment is to be carefully chosen and physical therapeutics continued. Parents should be taught that the child is to be especially cared for during all the years until growth is attained, the object being to preserve general health, keep the spine straight, and help paralyzed limbs keep up with the rest of the body. Besides electricity, given three times a week for three weeks at a time and then resting three weeks, careful direction of physical exercise and reeduca-
tion of muscles will be important. Results of thirty-nine cases in the regressive and chronic stages, treated during the last two years in my clinic, have demonstrated the value of the methods outlined above.

CONCLUSIONS.

Treatment of this disease and its results should embrace:

1. Prophylaxis; mouth and throat hygiene, toothbrush, nonirritating douche and gargle, mental preparations.

2. Rest, in acute stage, and prevention of fatigue at all stages.

3. As aftertreatment; prosthetic appliances, passive motion, massage, electricity, hydrotherapy, mechanical vibration, exercise.

4. Prevention of crooked spine and keeping up function and growth in damaged members; reeducation of nerve and muscle.

5. Preparation for suitable surgical measures; continuance of treatment after surgery.

NEOSALVARSAN.

Intramuscular or Intravenous?

By Robert Ormsby, M. D., New York.

"Under which king, Benzonian: speak or die." Though things may not be altogether as bad as that yet, I must admit that I never gave an intravenous injection of salvarsan without to a certain and a very appreciable extent feeling disturbed. It certainly always appeared to me that I was playing with edged tools, and, from my point of view, if any disaster occurred to my patient I would feel morally responsible if not actually so. I am now speaking of the injection of salvarsan (in contradistinction to neosalvarsan), but since the introduction of the latter I have abandoned the use of salvarsan altogether, either intramuscularly or intravenously. I used salvarsan intramuscularly only a few times, and when I saw the direful effects which were produced I quickly abandoned that method in favor of the intravenous route. As I said before, I never performed the operation intravenously without some trepidation, yet I was willing to undergo the anxiety and worry incident to that operation rather than run the risk incurred by injecting salvarsan intramuscularly.

With the discovery and introduction of neosalvarsan the whole aspect of affairs was changed—neosalvarsan, introduced either intravenously or intramuscularly, became more or less a matter of daily routine, and on account of its safety became a safe and sane remedy, with none of the gruesome characters of salvarsan. When we remember the amount of detail and care necessarily expended in preparing for the intravenous introduction of salvarsan and the undoubted element of risk which always accompanied the operation, it was no wonder the operation hung fire and many worthy and conscientious doctors adhered to the use of mercury intramuscularly altogether. These preliminary details bring us to the beginning of the article, intramuscular or intravenous. By which route shall we introduce neosalvarsan? We have, I think, eliminated salvarsan as a remedy; therefore we can dismiss it from consideration. Of course, there will be many opinions, and opinions will be pretty fairly divided, but the more often I use neosalvarsan, the more inclined I become to the intramuscular method. While we had nothing but salvarsan we had no option but to use the intravenous route, because any other method was beset by so many difficulties and dangers, but now we are in a new position, and we find the use of neosalvarsan intramuscularly attended by no danger.

If a six inch quadrilateral of the upper and outer border of the glutei muscles is selected as the site of injection there is very little pain. To further prevent pain I inject with an ordinary hypodermic syringe an ampoule of urea and quinine hydrochloride into the site selected and leave the needle in situ for twenty minutes or more. It is the same needle I use for the subsequent injection of the neosalvarsan solution; so I save the patient needless pain by leaving the needle in situ while I prepare the solution of neosalvarsan. This employs me for the twenty minutes required for the absorption of the urea and quinine hydrochloride, and if it requires longer than twenty minutes so much the better, because to produce anesthesia in this way it requires at least twenty minutes. It is, of course, absolutely imperative that the instruments used should be scrupulously clean. The ampoules and the files should be left in alcohol, and distilled water be freshly boiled for the occasion. Ten centigrammes of this freshly boiled water, without salt, is to be used for dissolving the neosalvarsan and is amply sufficient. The syringe which is to be used for the injection of the neosalvarsan, and which should be graduated for centimetres, is now charged with the solution and screwed on the needle which has been left in situ, and slowly the solution is injected into the same situation occupied by the urea and quinine solution, and the needle withdrawn and the aperture treated secundum artem. If these directions are carried out strictly there will, I think, be no doubt as to which method is the best, and you can go to bed at night and, like Macbeth, "tell pale hearted fear it lies, and sleep in spite of thunder."

Martin, of Hot Springs, Arkansas, recommends using larger doses: I recommend giving smaller ones. The only difference is that I demand more frequent injections. Nine decigrammes is most frequently used, but I think this amount excessive, and almost bound to cause reaction and disturbance. Five decigrammes for men and four for women is amply sufficient. Give this dose once a week for four weeks certainly, and then more, if required, and you will have every satisfaction both to patient and physician. A five decigramme injection with the precautions already laid down will
cause no reaction whatever, and there need be no dread of any ill effects. I myself have used nine decigrammes, but prefer the smaller dose frequently repeated. I will leave to others the maintenance of the opposite view, a preference for the intravenous method.

I will close with telling what occurred once in my office. I told a man I was going to use neosalvarsan. I said, in answer to his inquiry, that I was going to insert it into a vein. His eyes at this information became a little larger than good sized saucers. The fright and agitation of this individual were so extreme that I thought that perhaps these were largely responsible at times for the shock and disturbance attending this operation; and then, I think, began my own disinclination to use this method of medication. It is needless to say that I chose the intramuscular method for this gentleman, and he bore it without flinching.

368 Lexington Avenue.

INTERPRETATION OF PAIN IN SURGICAL EMERGENCIES.*

By Lilian K. P. Farrar, M. D.,
New York.

The surgeon of to-day has many aids in diagnosing the acute surgical conditions and arriving at a decision when or when not to operate in a given case. Medical teachings, his general knowledge of surgical diseases, his own experience in operative cases, or the experience of his colleagues, together with the history of the patient and course of the disease, of attacks past and present; the patient's general condition, his facial expression, temperature, pulse, and respiration; blood pressure, blood count, either absolute, relative, or differential; uranalysis and condition of the digestive tract, or menstrual history, are all of importance in making the diagnosis. But the patient has little or no knowledge of surgical diseases; at most it is limited to the experience of some friend or relative with somewhat similar condition. Often he does not know whether he has fever or not, certainly does not know the condition of his pulse or respiration, whether his white cells are increased or diminished, or their relative value; but one factor he has, and when he has it he usually knows it—and that is pain. It is pain that oftentimes brings the patient to the surgeon, and it is on the patient's estimate of his pain that the surgeon must rely in making his diagnosis, for no instrument has as yet been devised to measure the amount of nerve irritation produced in any pathological condition. Consequently the surgeon, even after he has had the assistance of the thermometer, the microscope, and the sphygmomanometer and laboratory technic, must often base his judgment of the gravity of the condition on the amount and kind of pain the patient has as it is related to him by the patient, or as he can himself estimate it by the patient's expression. It is from the patient's point of view that I wish to consider to-night a few of the surgical emergencies that we most frequently encounter—the importance of pain, its occurrence in these emergencies, and what value the patient can give to it as a symptom. As it is the only one constant symptom the patient knows, I shall not consider any other in following the course of a disease, except in its relation to this.

Surgical emergencies: By this we mean surgical cases in which it is considered necessary to operate on, or shortly after, the admission of the patient to the hospital in order to preserve the patient's life. In the last yearly report of Bellevue and Allied Hospitals (Gouverneur, Harlem, and Fordham) there were 6,842 operations, of which 576 were obstetric operations, leaving 6,266 total surgical operations. No record is kept of actual surgical emergencies, but 2,304 laparotomies (or opening of the abdominal cavity), including hernia, were performed. That is, more than one third of all surgical operations in Bellevue and Allied Hospitals for that year were done for abdominal conditions, or what we call major work. If we now consider in this number of 2,304 abdominal cases the three types of cases in which operation was most frequently performed, we find:

I. Appendicitis—416 cases, 2,304 abdominal cases, 758 abdominal gynecological operations, 6,266 all operations.

II. Ectopic gestation—58 cases, 1 in 34.

III. Hernia—54 cases, 1 in 39.

This does not include all of the acute surgical conditions, nor is it to be considered as a record of surgical emergencies, which would require a more intimate knowledge of the histories of the cases that is neither possible nor to the purpose of this paper; but what I do wish to bring out by these figures is that the three acute surgical conditions for which the greatest number of laparotomies were performed in this year are characterized by pain, and as pain is the chief symptom the patient has by which he may judge of the seriousness of his illness, it is important to have some knowledge of the most common surgical diseases, their course, and possible termination, in order to understand how best to interpret this symptom.

I. Appendicitis. 416 cases, 1 in 54 of 2,304 abdominal cases, 1 in 15 of 6,266 operations.

On the right side of the body, on an imaginary line from the umbilicus or navel, to a bony point on the right hip, called the anterior superior spinous process of the ilium, and two inches from this process, is McBurney's point, first described in 1886 by Dr. Charles McBurney, of this city, as the place where lies the famous narrow "round part of the intestine," as Gray, the anatomist, calls the appendix. The appendix of the cecum, as it is called from its attachment to that part of the intestine known as the cecum, or the vermiform appendix, from its wormlike appearance, is in its normal condition about three and one quarter inches long (its extremes being from one to nine inches), and from five to six millimetres in diameter, resembling in appearance the garden worm boys dig for bait. One end opens directly into the cecum, the other is closed at the tip, and lies free and normally unattached in the abdomen. It is sometimes found

*An address delivered under the auspices of the Public Health Education Committee of the Medical Society of the County of New York, at the New York Academy of Medicine, February 5, 1913.
pointing inward, at other times upward, or lying behind the cecum and then turned upward, again downward and inward, or directly downward into the true pelvis. It consists of two layers of muscle covered with peritoneum, which is the mucous membrane lining the abdominal cavity and covering over the intestines, and it is also lined with mucous membrane, which is continuous with that lining the cavity of the cecum.

Clinical varieties of appendicitis: There is no arbitrary way of dividing appendicitis into classes until the appendix reaches the pathologist, but the general surgeon classes the inflammation under one of five or six divisions, according to the severity of the symptoms.

1. Colic of the appendix: Characterized by sharp attacks of pain in the region of the appendix, occurring in patients who have an appendix bound down by adhesions, with the tip often bent upon itself and attached to some neighboring portion of the intestine, or to the tube or ovary, with resulting permanent kinks in the appendix. Often colic is due to strictures or narrowing of the lumen of the appendix, as the result of obstruction following such an adhesion or kinking. Often atrophic retrograde changes in the appendix are the cause of severe intestinal colic. If the organ is removed at this stage, there is usually no inflammatory change found microscopically in its tissue. This attack may be the first and last suffered by the patient, or there may be an interval varying from years to a few days or usually weeks, and then a second similar attack, or series of attacks, occurs. In the interval the patient may be entirely free from pain, or experience a slight soreness or a bruised feeling in this region. If constipation occurs, this soreness may be increased. Often women notice the occurrence of pain only during the menstrual period, and the pain passes for dysmenorrhea, or painful menstruation, while the real source of pain is the appendix, which becomes more painful at the time when the pelvic organs are normally congested.

2. Catarrhal appendicitis: This may be a later stage of the first condition, or the initial stage. The mucous membrane lining the cavity is congested, showing a mild degree of inflammation. Pain is less acute than in colic of the appendix, but the symptoms are of longer duration and greater soreness follows. Subsequent attacks may occur at long or frequent intervals, with pain perhaps entirely absent, or present in but slight degree, during the interval.

3. Ulcerative appendicitis: (a) Without abscess. This is an acute suppurative condition, the wall being invaded by bacteria, with resulting localized peritonitis. In the wall of the appendix is an ulcerated spot, usually at the site of an old constriction, or where a concretion is enclosed in the appendix. The wall is thinned at this ulcerated area, and easily perforated if early operation is not performed. Pain is severe and constant in this type. During the interval of acute attacks a sore, tender area is usually present at or about McBurney's point. The patient naturally protects that side instinctively wounding off a possible blow or injury. sits or walks with greater caution, and is subject to sharp, knife-like pains directly through the body. Palpation of this region evinces acute pain, the muscles becoming rigid to guard the sensitive organ.

(b) With abscess: Infection progresses sufficiently slowly for Nature to form a limiting barrier or membrane, and wall off the infection at this ulcerated spot from the general abdominal cavity; and an abscess forms about the appendix which may be now in its ulcerated condition or, in severe cases, have become gangrenous and sloughed off from the intestine. This abscess wall, if not opened by the surgeon, may burst and infect the general abdominal cavity, with general peritonitis or pyemia resulting. If recovery follows, other attacks are liable to occur, until the diseased appendix is removed.

4. Acute perforation of the appendix: This occurs in appendices where there are old ulcerations or strictures. The onslaught is so sudden that Nature does not have time to wall off the intestine with an inflammatory membrane, and so limit the infection to the region of the appendix. The infectious matter is poured out from the perforation in the appendix into the general abdominal cavity, and general peritonitis follows. This form of appendicitis is characterized by sudden onset, the most intense pain, with symptoms of collapse. The course may be either recovery or peritoneal septicemia with symptoms of profound toxic poisoning, without much pain or tenderness in its terminal stages.

Conclusion: Fortunately Nature usually gives ample warning. There is rarely an overwhelming fulminating infection where there has not been a history of previous attack, or several attacks, and sufficient time for operative measures. The colicky or sharp pain of the early invasion, and even the soreness, pass off, and, with each successive illness lived through, the hope and expectation grow that each attack will be the same as the others—even though the guide, pain, is more acute, more persistent, with each recurrence.

II. Ectopic gestation: 58 cases; 1 in 30 of 2,304 abdominal cases; 1 in 13 of 758 gynecological abdominal cases; 1 in 108 of 6,260 operations.

The term, ectopic gestation, derived from the Greek ἔκτω (out of) and τόμος (place), is used to describe gestation which occurs anywhere but in the uterus or womb, i. e., out of its normal place. We speak of an interstitial pregnancy, or pregnancy in the wall of the uterus or in one horn of a malformed uterus; of tubal gestation, as gestation in the tube attached to the uterus; ovarian, if in the ovary; or abdominal, if development has gone on in the abdomen. The terms "false conception" or "missed conception" were commonly used before the nature of this condition was known. Gestation is neither false nor missed, it is simply ectopic, or out of place. The pelvic organs in women consist of the uterus and two ovaries, one on either side, attached to the upper portion of the uterus, and between each ovary and uterus on either side is a narrow hollow tube of about three inches in length, and from eight to fifteen mm. in diameter (or the size of a lead pencil) composed of muscle lined with mucous membrane and covered with peritonum, resembling somewhat the appendix in appearance. One end opens directly into the uterus; the other end is patent, and into this the ova are conveyed.
from the ovary to the uterus. The ovum is commonly impregnated in the outer one third of the tube, and passes then into the cavity of the uterus. If now, for any reason, the impregnated ovum, which is to become the fetus or child, is prevented by a constriction or kinking of the inner portion of the tube from entering the uterus, as it normally should, development of the ovum then goes on in the tube, which is not constructed to receive it. The wall of the tube is thinned and stretched by the growth of the ovum, and, except in rare instances, rupture of the tube or expulsion of the ovum through the abdominal end of the tube occurs with severe shock and internal hemorrhage. If the condition is not recognized and an operation performed, death may result from the internal hemorrhage. In early cases the blood may clot and check the flow, especially if only a small blood vessel has been opened. If the ovum has been destroyed, in an early case, there may be an absorption of tissue, but usually the patient goes on to a second hemorrhage, or repeated hemorrhages, with greatest danger of a fatal termination—or, if recovery, peritonitis, possibly later suppuration and ulceration through other tissues, or may persist indefinitely as a sac containing the fetus.

Conclusion: The symptoms to give warning of this condition are rarely absent. Usually a menstrual period is overdue, or one of two periods even have been missed, with intermittent flow and attacks of sharp, lancinating, tearing pain in one side or toward the back. A persistent achiness, sore feeling is left after the bright blood or the brownish discharge has ceased. The patient often considers she has had a threatening or completed miscarriage, and neglects the symptom of pain—the indication that gestation is still going on.

III. Strangulated hernia: 54 cases; 1 in 42 of 2,304 abdominal cases; 1 in 116 of 6,266 operations.

Hernia is the condition commonly known as rupture. The word is derived from πρόω, a "sprout," and in the surgical use of the word means a tumor formed by a portion of an organ (hence the term "sprout") or an entire organ which has escaped from the cavity in which it is usually contained, either by forcing its way through a natural opening or by making for itself a new opening, until it comes to lie outside the body cavity or within some other cavity. The most common form of hernia, and the one we shall consider to-night, is abdominal hernia, of which there are several varieties, according to the abdominal opening through which the organ has escaped. 1, inguinal; 2, femoral; 3, umbilical. These three openings are normal for the passage of 1, the cord or round ligament; 2, the bloodvessels and nerves; and 3, for the umbilical cord in fetal life, but they should not be open sufficiently far for the passage of any other organ or portion of an organ. If for any reason there is a weakness at any one of these openings, and undue pressure occurs, as in heavy lifting or straining, a portion of the bowel or omentum (even appendix, bladder, tube, ovary, and, in rare instances, uterus) may enter into one of these openings, carrying ahead of it a fold of peritoneum, and, thus forcing its way between the muscles, passes through the abdominal wall until it lies outside the body just under the skin. This pouch of peritoneum which the omen-
tum or intestines has pushed out of the body cavity, and within which it lies, is called the "sac" of the hernia, and its narrow part, where it passes through the opening in the abdomen, is the "neck" of the hernia. If this tumor can be pushed back again into the abdomen, we say the hernia is "reducible"; if it cannot be pushed back it is "irreducible." If there are symptoms of intestinal obstruction, (i.e., the contents of the bowel cannot pass through the loop of prolapsed intestine), the hernia is "obstructed" or "incarcerated." If now the constriction in the neck of the sac is so great as to interfere with the circulation, the hernia is "strangulated," and as its blood supply is cut off, the destruction of this portion of bowel soon begins and gangrene quickly follows, with resulting sloughing of the strangulated loop.

1. Reducible hernia: In this type of hernia pain is only a slight or negative factor. As the bowel enters the sac, or is pushed back into the abdominal cavity, there may be a momentary feeling of pain or discomfort, but on palpating the mass it is insensitive and examination gives no increase of pain, as in tumors in the same region.

2. Irreducible hernia: As long as there is no obstruction to the passage of the contents of the bowel there may be no feeling of pain, or only slight discomfort or a dragging sensation. On examination, the mass is insensitive, and only attempted reduction causes pain. Many cases go on for years with no further symptoms, but if at any time the adherent bowel becomes clogged, and the passage of the contents arrested, or if the omentum which is in the sac has its blood supply cut off, the third type occurs.

3. Obstructed or incarcerated hernia: The tumor is now increased in size and markedly painful, pain being severe even if the patient is at rest, and no palpation of the hernia attempted. If the obstruction is not soon relieved, either by the contents of the bowel passing on through the intestine, or by the surgeon's opening the hernial sac and allowing them to make their escape, or the circulation of the omentum or other organ to be restored to normal, the fourth type results.

4. Strangulated hernia: The condition is now most serious, the patient suffering intense pain, and immediate relief for the imprisoned loop is necessary, if it is to be saved, or, even if amputated, if the patient's life is to be saved. If help is not given, gangrene follows, and with its occurrence there is a cessation of pain; the feeling of relief is often now so great that the patient hopes the condition has improved for the better, but collapse and death soon follow.

Conclusion: Pain is, therefore, in hernia, an index of the inflammatory process going on in the tumor. While the passage of the fetal contents is undisturbed, and the circulation not interfered with, pain is light, if present at all; but with disturbance of contents or blood supply, the pain increases in proportion to the disturbance until actual death of tissue results.

Final conclusions: In following the course of three of the most common acute surgical conditions I have endeavored to show that the inflammatory process going on in acute surgical diseases is accompanied by characteristic pain—that pain
definite in character has a definite cause. Nature does not permit any severe injury to the body tissues without sending a message of protest. The nerves of the body are the wires of transmission, and lie quiescent if the tissues are in a normal state. But if the tissues have received insult or injury, the nerves take up their work of transmission. By the report of pain the surgeon is able to locate the organ affected, to judge the degree of injury, and to give a prognosis of the result, whether he can see the inflammatory process in the organ affected or not, for the process is the same in whatever part of the body it is found. The hernia one can see enlarge and redden as it becomes obstructed is no more dangerous to life than the ulcer eating its way through the wall of the appendix to pour its infection into the unprotected abdomen, or the ectopic gestation opening up bloodvessels preparatory to a fatal internal hemorrhage, but it is much easier to convince a patient of the urgent need of an operation in an obstructed hernia than in an acute appendicitis or ectopic gestation. Consider 416 cases of acute appendicitis, 68 cases of chronic appendicitis, in comparison with 54 cases of strangulated hernia and 567 cases of chronic hernia. Unlike the experience of childhood, when the things we could see were not half as fearful as the things hidden in the dark, pain plus the sight of a tumor undoubtedly influences to operation far oftener than pain hidden in the abdominal cavity, even though that pain may be of a much more severe type; but the suppurative process goes on equally inside or out and Nature's messenger records the pain, as a guide to him who will read her well.

40 West Ninety-sixth Street.

PRIZE ESSAYS.

Questions for discussion in this department are announced at frequent intervals. So far as they have been decided upon, the further questions are as follows:

CXXXV.—How do you treat burns? (Closed June 10th.)

CXXXVII.—How do you treat cholera infantum? (Answers due not later than July 15th.)

CXXXVIII.—How do you treat threatened abortion? (Answers due not later than August 15th.)

Whoever answers one of these questions in the manner most satisfactory to the editor and his readers will receive a prize of $5. No importance whatever will be attached to literary style, but the award will be based solely on the value of the substance of the answer. It is requested, but not required, that the answers be short, if practicable no one answer to contain more than six hundred words; and our friends are urged to write on one side of the paper only.

All persons will be entitled to compete for the prize whether subscribers or not. This prize will not be awarded to any one person more than once within one year. Every answer must be accompanied by the writer's full name and address, both of which we must be at liberty to publish. All papers contributed become the property of the JOURNAL. OUR READERS ARE ASKED TO SUGGEST TOPICS FOR DISCUSSION.

The price of $2 for the best essay submitted in answer to Quest. CXXXIV has been awarded to Dr. John H. Shaw, of Philadelphia, whose article appeared on page 30.

PRIZE QUESTION CXXXIV.

THE TREATMENT OF MUSCULAR RHEUMATISM.

(Concluded from page 32.)

Dr. Meyer A. Rabinowitz, of Brooklyn, N. Y., says:

Muscular rheumatism is a dangerous diagnosis for a conscientious physician to make. The correct diagnosis may be either aortic aneurism, cancer of the pleura, tabes, osteomyelitis, spondylitis deformat-

ans, bone tuberculosis, syphilitic periostitis, lead poisoning, morphine habit, alcoholic neuritis, trigonitis, gonorrhreal sepsis, onset of an acute infection (typhoid, influenza, variola, anterior poliomyelitis, meningitis), intestinal autointoxication, sacroiliac joint relaxation, local disease of muscle, hematoma due to trauma, hematoma following vascular change (as in typhoid, sepsis, jaundice), muscular cicatrices following fibrous myosites, atheroma of arteries in muscle (as in intermittent claudication), muscle abscess, infarct, gumma, eocrinococcus cyst, or new growth.

Treatment begins with diagnosis, and the diagnosis of muscular rheumatism must be made by exclusion. It is usually of acute onset following exposure and fatigue and the muscles affected—usually neck, back, or chest—are painful on movement and tender on pressure.

During the acute stage, within the first twenty-four hours, the following will cut short the disease:

1. Hot mustard foot bath; then to bed.
2. Plenty of blankets about body and hot bottles to feet.
3. Dover's powder, one dose of ten grains for adult and plenty of fluids.
4. A brisk saline cathartic; restricted fluid diet.
5. Internally if necessary to relieve pain and temperature, and induce perspiration, full doses of sodium salicylate.
6. A hypodermic injection of one fourth grain of morphine sulphate over site of pain, if very violent and acute.
7. Locally, over site of pain, dry cupping or a few leeches.

In the subacute stage:
1. Diet. Reduce proteids, increase fluids, vegetables and cereals.
2. Drugs:
   (a) Add potassium iodide, five grains, three times a day to the sodium salicylate.
   (b) Acetphenetidin, three grains every three or four hours if an analgesic is needed
   (c) No codeine, morphine, opium, for the drug habit if fastened upon the patient is much worse than the original pain.
3. Locally, the following are of decided value:
   (a) Massage, especially following hydrotherapy, and using a liniment as a lubricant.
   (b) Liniments—usually combinations in various proportions of tincture aconite, turpentine, chloroform, ether, and alcohol.
   (c) Belladonna plaster may be left on for several days.
   (d) Mustard pastes.
   (e) Electricity.
   (f) The actual cautery is an excellent counterirritant. Use a smooth broad platinum point at white heat, applied with rapid strokes, broadly and superficially, only for an instant. This is especially applicable in muscular rheumatism of the back.
   (g) Injections of physiological saline to the amount of from five to ten cubic centimetres, at most painful points in muscles are of decided and rapid benefit.
   (h) Hydrotherapy is placed last, but is not least in value. Hot pack—electric or hot air—locally until perspiration is excited. Circular douche 95°F. follows for one minute; then Scotch douche fo-
cally at 110° and 70° F. for one or two minutes, ending with massage, striking and kneading the muscles for twenty minutes.

Dr. Lionel C. Charbonneau, of Brooklyn, N. Y., remarks:

The word rheumatism is employed indiscriminately by the profession to cover conditions bearing no relation to the etiology of muscular rheumatism.

When will physicians become specific in their nomenclature, more deliberate in their physical examinations and erudite in diagnosis? A little more painstaking, a little less hurry—and many perplexing situations would be avoided. Frequent uranalysis, constant use of the sphygmomanometer, systematic application of the stethoscope and paying particular attention to detail would strengthen the medical man in his profession—enlarge his clientele. There would be less cry against hospital and dispensary abuses. The poor we always have and hospitals, dispensaries, and contract work must ensure. Another word before coming to my subject. Our institutions of medicine are responsible for the pitiful lack of psychic, mental, organic, and physical therapeutic knowledge possessed by graduates in medicine. If our professors in therapeutics did less unreasonable questionings and listened more to the smoother inner voice of conscience, left their preconceived ideas in the background, showed less prejudice, the mental growth of our graduates would not be stunted in physical, organic, and mental therapy.

Given a case of acute muscular rheumatism, with some fever and rapid pulse, the patient is put to bed, small doses of calomel are prescribed, followed by a saline. Sodium salicylate and double the quantity of sodium bicarbonate are given every two or three hours in one half a glass of vichy. The patient remains in bed for from one to four days. The diet consists of milk, fruit, and gruel. If pain or soreness continues after the fever is under control a mild and moderate massage is given, followed by the use of an ointment of:

- Methyl salicylate, \( \frac{1}{100} \) m. \\
- Menthol, \( \frac{1}{100} \) m. \\
- Tincture of capsicum, \( \frac{1}{100} \) m. \\
- Ointment of rose water, g. s. ad. \( \frac{1}{100} \) m.

M. S. To be smeared over painful areas.

Patients with acute or chronic muscular rheumatism without constitutional disturbances, if possible, are treated at the office. At times a lumbar is so severe that the patient cannot be moved. Large doses, from ten to twenty grains, of sodium salicylate, in one half glass of vichy is given each hour until relieved, then if the least soreness remains the patient is sent to the office for further attention.

The most frequent varieties of muscular rheumatism are lumbar, torticollis, pleurodynia, and rheumatism involving the muscles of the scalp. Uranalysis invariably shows that the waste and nitrogenous products are freely absorbed, there is intestinal indigestion, and in acute cases history of exposure to excessive cold or heat and draft. In acute cases the diet is limited to fruit, vegetables, soups, bread, and butter, and plenty of vichy and exercise in the open air is strongly urged.

In lumbar the 500 candle power lamp is applied to painful area for fifteen minutes, followed by the static wave current for twenty minutes and concluding the treatment by giving long sharp sparks from the brass ball electrode from one to two minutes. Acute lumbar is frequently cured with one such treatment; chronic cases require from one to four weeks.

In torticollis, the high frequency current with the vacuum tube, emitting a one half to one inch spark, continued in light contact with the skin from ten to fifteen minutes, given each day until cured. The same technic holds good for pleurodynia or the muscles of the upper or lower extremity. The treatment for muscular rheumatism of the scalp, if there is an abundance of hair, is different in technic. Place the patient upon the static platform, shoes off. The static wave is given, with the multiple pronged electrode in the operator’s hand, sweeping the electrode over the scalp, the treatment lasting from ten to fifteen minutes.

All chronic cases of muscular rheumatism are given autocondensation from twelve to twenty minutes, 400 to 800 milliamperes amni-teried. Solution of nuclein, five minims, or desiccated thyroid gland, one grain three times a day. The following capsule at bedtime:

- Phenolphthalein, \( \frac{1}{100} \) m. \\
- Acid sodium oleate, \( \frac{1}{100} \) m. \\
- Menthol, \( \frac{1}{100} \) m. \\
- Salicylic acid, \( \frac{1}{100} \) m. \\
- Magnesium carbonate, \( \frac{1}{100} \) m.

M. Divide in capsules, No. xi.

Meat and eggs cut down and sometimes discontinued while under treatment.

In two cases of chronic muscular rheumatism of years’ duration the patients failed to obtain absolute relief under medicinal, dietetic, physical, or vaccine treatment, hypodermic injections of a twenty-five per cent. solution of magnesium sulphate, twenty minims, three times a week, cured the one in four weeks, the other in six weeks. These were treated and discharged cured in 1911 and have remained free from stiff or sore muscles since. Physicians not in a position to treat with electrical modalities will often obtain brilliant results by giving mild and moderate massage over painful areas—the process is slow, but satisfactory.

---

**Therapeutic Notes.**

**Treatment of Anemia in Children.**—H. Lowen- 

burg, in the American Journal of Diseases of 

Children for September, 1912, advises the admin- 

istration of intramuscular injections of the following 

preparation in severe cases of anemia in children:

- Ferri citratis, \( \frac{1}{100} \) m. \\
- Soda cacoalectis, \( \frac{1}{100} \) m. \\
- Soda glycophosphatis, \( \frac{1}{100} \) m.

M. ft. soluto.

Weekly or biweekly injections should be given. The site and especially the manner of injection are
important. The needle should be thrust deeply into the muscles on the posterior and outer aspect of the arm, and its direction should be at right angles to the skin surface. A slight stinging sensation should alone result. A rapid increase in the hemoglobin and erythrocytic count results from the injections.

**Treatment of Hepatic Abscess in Amoebic Dysentery.**—Chauffard, in *Bulletin de l'Academie de medecine* for February 23, 1913, reports a case of hepatic abscess by bronchial fistula of five months' standing, due to amoebic dysentery, in which subcutaneous injections of emetine (hydrochloride probably; though the salt used is not mentioned), as recently recommended by Rogers, gave most excellent results. The patient had been expectorating bloody material to the amount of from one half to one pint daily, was feverish, and had two or three loose bowel movements daily. Though the case was about to be operated on, it was decided to try emetine first. Six injections of 0.01 gramme (two-third grain) each were given in the course of five successive days, two being administered on the third day.

On the second day the patient already felt distinctly better. Although even on the first day the amount of expectoration was somewhat lessened, on the third day it was reduced to two ounces and on the fourth to one and one-half ounce, while on the fifth the patient expectorated but three times in the entire twenty-four hours, this being, in fact, the last sputum obtained from the case. The temperature fell to normal on the second day and remained normal subsequently. The blood examination showed corresponding improvement, an ulcer previously observed in the rectum promptly healed, radiography showed a return of the lower pulmonary area and diaphragmatic vault to normal, and the patient gained in weight. The results were so prompt that no other explanation seems to the author admissible than that of a direct *therapia sterilis*. Six weeks after the treatment had been discontinued there was no sign of recurrence.

The injections caused but little pain and no local induration, no anorexia, nausea, malaise, change in the pulse rate or significant fall in the blood pressure were noted.

**A Substitute for Kuhn's Aspiration Mask.**—T. W. Williams, in the *Journal of the American Medical Association* for March 8, 1913, states that all the benefits from Kuhn's mask can be obtained in a simple manner by breathing through a section of a small catheter (about No. 10 French), or a straw or quill. As with the mask, the result is a gradual, deep inspiration; the air is then held a few seconds and suddenly expired. Negative compression of the lungs is thus produced, and blood sucked from the right chamber of the heart into the lungs. When the heart is weakened, and it is tiring to overexercise for instance, and there is pain from overdistention of the right chamber, if the patient will lie down for five minutes and breathe in the manner described through a quill toothpick or even through his teeth, immediate and remarkable relief will be experienced. The procedure is also often efficacious in nervous excitement and insomnia, and it is the author's custom to instill anemic and nervous patients to carry it out for five or ten minutes upon lying down at night.

**Prevention and Treatment of Cutaneous Affections in the Insane.**—To A. Luther (Journal of Mental Science, January, 1913) is credited a discussion of the skin affections occurring in the insane as secondary results of treatment by prolonged baths and the wet pack. In furunculosis, this author presents each commencing furuncle and the adjacent parts with five or ten per cent. salicylic acid collodion. If this treatment is employed early enough the furuncle in most instances dries up; in other cases, where it has gone on to softening, it remains small and only a little thin pus forms. Painful tension is speedily removed, and there is a high degree of probability that further infection will be prevented. When painted with tincture of iodine, furuncles will often shrivel; in addition, this plan the use of water must be absolutely avoided.

Where eczema occurs, no course is open but to discontinue the baths; powders and a desiccating paste will then bring about a speedy cure.

In ringworm, Luther has found a five to ten per cent. chrysarobin collodion very useful; in recent cases one daily painting generally suffices. Tincture of iodine yields far less certain results.

A measure useful in the prevention of these diseases and which permits of the continuance, in part at least, of hydrotherapy in the form of the wet pack, is to substitute for water partial or complete packings with a three per cent. boric acid solution. If the cloths are allowed to dry on the patient the acid becomes deposited on the body in the form of a fine powder, which acts subsequently as a certain protective against infection. If an excessive loss of heat in decrepit patients is apprehended the solution can, of course, be applied warm. Equally as satisfactory results can be obtained in the case of the prolonged baths in adding boric acid to the water; in this connection, however, expense is an objection. Bath eczemas are, as a rule, readily cured by the boric acid pack treatment, and the latter does not contraindicate painting with salicylic or chrysarobin collodion if sufficient time is given for drying.

**Value of Atropine in Gastric Affections.**—Pletnev, in *Semenie medecine* for March 25, 1913, is credited with the statement that while atropine can at best only constitute a symptomatic measure in the treatment of stomach disorders, it deserves to be more widely employed than has hitherto been the case. Where gastric acidity is increased, atropine will reduce it indirectly, viz., by diminishing the amount of gastric juice secreted, so that a greater proportion of it will be neutralized by the alkaline mucus present. In pyloric spasm atropine also gives relief, probably in part by reducing acidity, but also by a direct "antispasmodic" action, as indicated by the fact that hourglass contracture of functional origin is similarly removed. In cases of overacidity or gastric ulcer pain is favorably influenced by atropine, which is preferable for this purpose to morphia because the latter, after temporarily reducing the secretion of gastric juice, excites glandular activity.
SUMMER DIARRHEA AND ITS TREATMENT.

In our last issue Doctor Lederle, president of the New York Board of Health, gave an outline of the efforts of the board in recent years to reduce infant mortality. That these efforts have been attended with good results—a large share of which is of course to be credited to the progressive work of pediatricians and hygienists—is graphically shown by the fact that while the death rate from diarrheal diseases for 1,000 children under one year was 44.28 per cent. in 1902, in 1912 this proportion had been reduced to 26.39 per cent. Encouraging as these figures are, however, there is ground for the belief that they could be materially improved if modern methods in the treatment of the diarrheal diseases which are familiar to specialists were resorted to more generally—methods which have given death rates, for the number of cases treated, below those usually obtained.

Limiting ourselves to those measures which have won the sanction of many careful observers, and also to the form of infantile diarrhea which by far causes the greatest number of deaths—that due to the toxins of pathogenic bacteria—we will describe those which are often neglected in the general field.

That the time honored dose of castor oil, to clear the intestinal tract of its pathogenic contents, is increasingly being replaced by calomel, owing to its antitoxic and bactericidal virtues, is familiar to every practitioner; but the trend of modern thought is to adjust the use of this agent to the status praesens of the patient. Thus, as taught by Lesage, patients who have high fever, foul smelling though not abundant stools, and considerable tympany, will do best if given one grain (for infants under one year, and two grains for those over that age) at one dose, while patients with low fever and copious diarrhea, although the abdomen is soft, show better results when from 1/10 to 1/15 grain is given every half hour or hour until ten or twelve doses have been taken.

A second feature too often overlooked is that milk favors the multiplication of intestinal pathogenic bacteria, unless the infant be breast fed; the milk under the latter conditions being antitoxic—the opposite of cow's milk after it has left the udder several hours. Hence the fact that artificially fed infants do best, when suffering from bacterial diarrhea, when nothing but water is allowed until the symptoms of intoxication subside. This should not however, be allowed to weaken unduly the infant or cause material emaciation. When feeding can be resumed, white of egg, which, as is well known, is a nutritious and readily assimilated protein, is to be preferred as soon as the stools lose their offensive odor. Finkelstein's Eiweiss Milch (casein albumen milk) is preferred by some, however, when there is marked weakness or emaciation. It is prepared as follows: A tablespoonful of essence of rennet is added to a quart of milk, which is then placed in a water bath at 108° F. for one half hour. It is then filtered slowly through cheese cloth. The coagulum is washed twice in a pint of water through a fine sieve, and forced through by beating with a wooden club. Then one pint of buttermilk is added. This is given in quantities corresponding to the usual feeding mixture indicated at a corresponding age.

Less complicated and probably quite as efficient is buttermilk, which is increasingly gaining advocates. Swarming as it is in its raw state with lactic acid bacteria, which have an inhibitory action on the development of other germs, it is especially efficient when the intestinal pathogenic organisms persist after the preliminary purgation and water diet. Besides, it is very nutritious and inexpensive. The infant will often refuse it, owing to its taste, but as recommended by Blackader, this may be obviated by adding cereal gruel and five grains (0.3 gramme) of cane sugar to the ounce of buttermilk. The latter may or may not be pasteurized. Morse obtained excellent results from pasteurized buttermilk,
milk, and prefers it to all other milk foods. We
are inclined to look upon pasteurization as a draw-
back, since it tends to impair the activity of the
lactic acid bacteria.

It is perhaps unnecessary to emphasize the fact
that cases differ and that the best results are ob-
tained where a careful diagnosis has been made.
Prophylactic and hygienic measures are also potent
auxiliaries, but most potent of all in the prevention
of infantile diarrhea is breast feeding, breast milk
itself being a powerful antitoxic.

THE COLLEGE OF SURGEONS.
The College of Surgeons presents something new
as an American medical society. Its object is not
only "to elevate the standard of surgery" in com-
mon with all other surgical associations, but also "to
provide a method of granting fellowships in the or-
ganization, and to formulate a plan which will in-
dicate to the public and the profession that the sur-
geon possessing such a fellowship is especially qual-
ified to practice surgery as a specialty." Its mem-
bers are to be known as Fellows, and they are urged
to append the letters F. C. S. to their names on pro-
fessional cards and elsewhere to indicate their mem-
bership.

Few of our readers will be inclined to deny that
both the profession and the public need some means
by which to determine whether a would-be practi-
tioner in a surgical specialty deserves their support
or not; so we welcome the college as an attempt to
fill this need. The plan is to list the names of all
practitioners who are competent to act as special-
ists in general surgery, or any of the surgical special-
ties, to give them a title by which they can be rec-
ognized as such, and to formulate requirements to
be met by future candidates for admission which
are proposed to be sufficiently exacting to render
the F. C. S. equivalent to a special degree in sur-
gery. The fact that it seems to have been taken
bodily from the custom of our British brethren
should not weigh for or against it, but we believe
that if the college is to succeed it must win the sup-
port and the confidence of the profession at large,
which seems to be noncommittal at present. To do
this it must make clear the benefits to be derived
by the general practitioner from the organization.

We do not believe that the founders have any in-
tention to create a monopoly of surgical practice, yet
it is not difficult to read such a purpose into the re-
port of the proceedings at their meeting, which con-
tains nothing definitely protective of the rights of
the general practitioner. We feel sure that they do
not wish to debar any surgeon from the practice of
such surgery as he is competent to perform, and
that they would be the first to condemn risking life
in an emergency by delay in order to secure the
presence of a more skillful surgeon. In almost
every small community of physicians one of their
number has proved to be a better surgeon than the
rest, and furnishes valuable services as such, al-
though his opportunities are too few to enable him
to compare favorably in skill with the city spe-
cialist, and we do not believe that the college wishes
to stop him in his good work. If we appreciate the
intention rightly it is to provide for the recognition
of certain specially trained men as specialists and to
prevent untrained men from posing for what they
are not, so it would seem wise if the statement were
made in positive terms that no wish exists to arro-
gate to the Fellows the exclusive practice of sur-
gery.

A very serious objection to the plan presented is
that it affords an opportunity for a certain set of
men to brand as incompetent, by refusing them ad-
mission, others as competent as themselves. We
would not be understood to intimate that the gentle-
men who are at present entrusted with the passing
on the merits of candidates for admission to the
college would do this knowingly or willfully, but
they have the power to do so, and history tells us
that such power has been abused in the past. It is
possible for fifteen men to form a clique which will
control the actions of so large a body as this in a
manner highly detrimental to the best interests of
the profession, and to render the possession of the
titular letters more a matter of favor than of merit.
This seems to us to be a source of serious danger
that needs to be guarded against. It is another mat-
ter that these gentlemen cannot be personally ac-
quainted with the merits or demerits of all candi-
dates, and may be misled; so far as this is concerned
mistakes are to be expected in every human under-
taking.

Finally, the information conveyed by the letters
F. C. S. is inadequate and may be misleading. The
college includes not only general surgeons, but also
ophthalmologists, otologists, and others who pretend
to no special skill outside of one limited branch of
surgery. Incompetent selfstyled specialists in vari-
ous surgical specialties abound and rely for success
mainly on their social qualities as "good mixers."
The public has no means of distinguishing them;
the profession a very imperfect one, through con-
sideration of hospital appointments and society
memberships. A certificate of study for six weeks
or more, or an appointment on the staff of a hos-
pital, is an invaluable asset for such a man. for the
certificate is seldom read in full, and the appoint-
ment, though only that of a clinical assistant, car-
rries the prestige of the hospital to support his as-
sumption of skill. At the school, or in the hospital, he may be considered an ignoramus and never allowed to do the most trivial operation without careful supervision, yet, outside, his pretensions are accepted, he performs serious operations, and it often takes years to disabuse the minds of his confrères and of the community as to his merits. We need a means of distinguishing the competent from the incompetent ophthalmologist, or otologist, quite as much as of marking the specially trained general surgeon, but here the plan of the college falls; it groups all competent specialists, as well as general surgeons, under the one title F. C. S. If it is wise for us to depart from our traditions, and to have specialists append certain letters to their names, we should be sure that those letters cannot be misunderstood. It would be better that the college should follow the spirit of the founders of the Royal College, rather than the letter of their proceedings, and mark each Fellow for what he is as a specialist. The F. C. S. could be given a Fellow who is a general surgeon, other letters to Fellows in the various specialties; then the profession would receive some real help from this organization.

THE DEATH RATE AMONG THE FEEBLE MINDED.

Basing their results upon the mortality of four thousand cases of idiots and feeble minded observed by them, L. Pierce Clark and W. L. Stowell reached the conclusion (see our issue of February 22d) that the feeble minded of all classes are shorter lived than those of normal intelligence. They divided the patients into two groups, those whom they called idiots and those of a higher grade whom they called simply the feeble minded. Among the former the death rate for a period of nine years was 19.6 per cent. Among the latter for the same period it was 6.5 per cent. During the same time and at the same place nearly eight thousand children of normal mentality were treated. The mortality among these was 3.38 per cent. This was an excellent control and makes the conclusions of these writers as to the comparative death rate of normal and feeble minded of great value, for under the same management and service, and during the same period, the comparison of the death rates is preeminently fair. Thus it appears to be unquestionable that the death rate of the feeble minded is double that of normal children.

A closer analysis of the figures which these observers furnish brings out the interesting fact that if the feeble minded succeed in passing the age of twenty their expectation of life is better than that of normal individuals. This is probably because institutional life serves to protect them against the infections, accidents, and acquired ailments to which the general adult population is exposed. The greatest divergence occurs in early childhood. At the age of three the feeble minded are six times more likely to die than are normal children. The disparity keeps up in a lessened degree until the "teens" are reached, when there is very little difference between the defectives and the normals. The lower the grade of mentality the higher the death rate. Thus, idiots have much less chance of reaching adult life than have morons and high grade imbeciles. The causes of death are exceedingly varied. Sudden death, or death after a very short illness, is exceedingly common. Idiots of the Mongolian type are especially apt to die young, and they have a habit of dying without warning. Pneumonia is a common cause of death in all types. Tuberculosis is also a frequent occurrence and, according to some observers, causes death in nearly forty per cent. of the cases. In the series reported by Clark and Stowell, tuberculosis was not of such frequent occurrence, this disease having been responsible for only ten per cent. of the total.

As feeble mindedness is without hope so far as cure of the affected individual is concerned, and as the longer the life of the defective individual the greater the danger to society through the reproduction of his own kind, it is hardly a matter of regret that Nature has a tendency to curtail this morbid perpetuation by an early death of the afflicted.

FRIEDMANN’S ANTITUBERCULIN VACCINE.

In a letter to the editor, which appears on page 104 of our present issue, Dr. George Gibier Ramboed places before the medical profession the composition of Friedmann’s vaccine. He states that the “vaccine is simply a homogeneous emulsion of live avirulent tubercle bacilli in plain sterile distilled water. The germ was isolated several years ago from a turtle, and the culture has been maintained since that time by transplantation on artificial culture media, according to the usual procedure.”

A MODIFIED WASSERMANN TEST.

Dr. L. O. Thompson describes, in the Archives of Internal Medicine for May, a method designed to overcome certain drawbacks of the original Wassermann and Noguchi tests, viz., the chance for error in that the human serum to be tested contains natural antisheep anticomplement, the difficulty of keeping a sheep, and the fact that the small quantity of serum used in the Noguchi test may not contain enough antibodies to cause binding of complement. In Thompson’s modific-
tion anti-human amboceptor, obtained after injection of washed human corpuscles into rabbits, is used. A ten per cent. solution of fresh guineapig serum is used for complement. From both rabbits and pigs the blood is obtained directly from the heart through a hollow needle, the animals surviving for future tests. The patient's blood is easily obtained, and in sufficient quantity, by withdrawal from a vein at the elbow with a syringe. A suspension of human corpuscles is used. In performing the test, incubation is continued for one hour, during which time the tubes are shaken several times to facilitate hemolysis. An elaborate system of controls, including eight different tubes, makes error impossible.

THE ETIOLOGY OF RELAPSE IN MALARIAL INFECTIONS.

James, in discussing the malarial fevers in the Canal Zone, in the Journal of Infectious Diseases. May, 1913, believes that a large part of the malaria prevalent in that district is due to the occurrence of relapses, and not to reinfections. This is apparently due to the presence, particularly in the bone marrow, of asexual parasitic forms, which when conditions are favorable increase and give rise anew to manifestations of the disease. In many instances it is found that infections treated insufficiently with small doses of quinine will in all probability relapse, as such doses, even in the mildest infections, serve only to render the asexual cycle relatively more susceptible. Also, the older the cycle, the more resistant to quinine it becomes. As a result of his observations, James believes that primary infections should be very vigorously treated in order to prevent the development of immune parasites. To that end he administers forty-five grains of quinine a day, in fifteen grain doses. By this method recurrent malaria has been practically eradicated from the Americans. When a relapse does occur, some other method than quinine by the mouth should be employed, preferably the intravenous method with high dilutions. This seems to more rapidly free the spleen and bone marrow from parasites than can be accomplished by hypodermic injections.

News Items.

The Lane Lectures.—The fourteenth series of the Lane medical lectures will be given by Sir Edward Schäfer, professor of physiology in the University of Edinburgh, on the evenings of September 3d, 4th, 5th, 8th, and 9th, in Lane Hall of Stanford University Medical Department, San Francisco. The subject of these lectures will be the Function of the Ductless Glands, Especially in Relation to Other Secretory Organs.

American Society for Physicians' Study Travels.—In our issue for July 5th we published an item concerning this organization, in which appeared the names of the newly elected officers of the society. We have since learned that we were in error in stating that Dr. William J. Mayo, Dr. Llewellys F. Barker, and Dr. Frank Billings were elected vice-presidents, as the society has no vice-presidents, but four presidents. Dr. James M. Anders, of Philadelphia, is acting president, and the other presidents, in the order of their election, shall, in the absence or disability of the acting president, be required to perform his duties.

A Merger of Medical Colleges.—The Atlanta College of Physicians and Surgeons and the Atlanta School of Medicine have been consolidated under the name of the Atlanta Medical College. Dr. W. S. Elkin will be dean of the new institution, and Dr. W. F. Westmoreland, president.

Manchester, N. H., Medical Society.—At a meeting of this society, held on the evening of June 20th, the following officers were elected: President, Dr. F. N. Rogers; vice-president, Dr. J. A. Wilkins; secretary-treasurer, Dr. E. A. Jones; censors, Dr. Gustave Lafontaine, Dr. W. H. Lyons, Dr. S. V. Fiske, Dr. G. S. Foster, and Dr. C. O. Coburn.

Smallpox in Norristown, Pa.—It is reported that there has been an outbreak of smallpox in Norristown, Pa., four cases having been reported within forty-eight hours. On July 1st thirty-seven physicians were busy all day vaccinating the hundreds who crowded their offices. So many persons have been exposed to infection that the health authorities fear a serious epidemic.

Massachusetts Medical Society.—At the one hundred and thirty-second annual meeting of this society, held recently in Boston, the following officers were elected: President, Dr. Walter B. Rice, of Clinton; vice-president, Dr. Lyman A. Jones, of North Adams; secretary, Dr. Walter L. Burrage, of Boston; treasurer, Dr. Edward D. Buckingham, of Boston; librarian, Dr. Edwin Brigham, of Brookline.

Medical Club of Harrisburg, Pa.—At the regular monthly meeting of this society, held on the evening of June 22d, the following officers were elected: President, Dr. Park A. Deckard; vice-president, Dr. George W. Bauder; secretary-treasurer, Dr. Edward K. Lawson, of Pennsylvania. The retiring officers were: Dr. W. V. Wilkes, secretary; Z. Shope, president; Dr. W. H. West, vice-president; Dr. John Harvey Miller, secretary; Dr. John Adam Sherger, treasurer. The paper of the evening, entitled History and Prevalence of Venereal Diseases, was read by Dr. Edward K. Lawson.

Death Rate in New York City.—During the week ending June 28, 1913, there were 1,152 deaths and a rate of 11.48 in 1,000 of population reported, as against 12.23 deaths and a rate of 11.90 in 1,000 of population for the corresponding week of 1912. This is the lowest weekly death rate that the city has ever experienced, the next lowest being that of November 2, 1912, when the death rate was 11.59. Scarlet fever, typhoid fever, diarrheal disease under five years of age, and deaths from these diseases, were considerably reduced mortality. On the other hand, diphtheria and pulmonary tuberculosis showed an increase in the number of deaths. Deaths from whooping cough, cerebrospinal meningitis, congenital heart and kidney diseases, and the pneumonias remained approximately the same as in the corresponding week of last year. Deaths of children under one year of age were 26 less, under five years of age 5 less, between five and sixty-five years 44 less, and above sixty-five years of age 12 greater. The death rate for the first twenty-six weeks of this year was 15.04 in 1,000, as against 15.66 during the corresponding period of 1912.

Personal.—Dr. Reid Hunt, chief of the division of pharmacology, United States Public Health Service, Washington, D. C., has accepted the professorship of pharmacology and therapeutics in the Harvard Medical School, succeeding Dr. Franz Pfaff, whose resignation was accepted last January.

Dr. James R. Niedegger, of the United States Public Health Service, has been elected professor of tropical medicine in the University of Maryland.

Dr. Wilfred Hamilton Manwaring, formerly assistant in pathology and bacteriology in the Rockefeller Institute, for Medical Research, has been appointed director of bacteriology and immunity at the Leland Stanford Junior University, San Francisco.

The degree of doctor of public health was conferred upon Surgeon General Rupert Blue, of the United States Public Health Service, by the University of Michigan, at the recent annual commencement of the institution.

Dr. William J. Mayo, of Rochester, Minn., has been elected foreign correspondent of the Academy of Medicine in Paris.

Dr. George Fay Gracey, professor of chemistry and toxicology in the University of Texas, has resigned to enter the practice of medicine in New York.
Gifts and Bequests to Hospitals.—A large portion of the estate of the late Francis H. Wyeth is devised to the Jefferson, Episcopal University, Methodist, Presbyterian and Lutheran Hospitals in Philadelphia.

By the will of Karl Hutter, who died in New York on June 15th, the German Hospital of Brooklyn will receive $10,000, and the German Hospital and Dispensary of Manhattan will receive one fourth of the residuary estate.

Dr. H. E. Wooster of Detroit has given $50,000 under the terms of the will of Frederick E. Driggs.

Among the bequests contained in the will of the late Mr. D. O. Mills are $5000 each to the Home for Incorruptibles, New York, and St. Luke's Hospital, San Francisco, and $50,000 to the American Red Cross Society.

Yale University will receive $475,000 from the estate of Dr. Francis Bacon, who died last year. The sum will be available for almost immediate use.

 './

Instruction in Sanitation by the Board of Health of Hot-Springs, Ark.—A recently appointed board of health of Hot Springs, Ark., is composed of the following members: President, Dr. J. C. Minor; secretary, Dr. William Turner Wootten; Dr. J. W. McClendon; Dr. William O. Forbes; Dr. Gaston A. Hebert, and Mr. Schaeleter, president of the State Board of Pharmacy. Dr. T. E. Sanders, city health officer; Dr. John S. Woods, county health officer, and Lee McLaughlin, Esq., city attorney, are ex-officio members of the board. The work of the department has been divided into two parts, instruction and practice, and it is the duty of the board that instruction of the public in sanitation does more good than coercion. The women's Civic Club has furnished its membership fifty inspectors deputized by the board of health to inspect butcher shops, bakeries, restaurant and hotel kitchens, milk wagons, and report on their sanitation markings, the highest average to receive a prize. It is said that the plan works well.

Medical Alumni of the University of Vermont Hold Annual Meeting.—The Alumni Association of the University of Vermont College held its annual meeting and banquet in Burlington, on the evening of June 24th. About sixty-five members were present. Dr. F. K. Jackson, of Burlington, was chairman of the committee of arrangements, and Dr. W. A. Smith, of Springfield, Mass., was toastmaster. The following officers were elected: President, Dr. Albert L. Bingham, '75, of Williston, Vt.; first vice-president, Dr. Mark R. Crain, '79, of Rutland, Vt.; second vice-president, Dr. John Wesley Cran, '88, of Colerain, Mass.; third vice-president, Dr. George Trueman, '86, of Stockbridge, Vt.; first executive secretary, Dr. Clayton G. Andrews, '97, of Canton, N. Y.; second executive secretary, Dr. Frederick B. Willard, '00, of Hartford, Conn.; treasurer, Dr. F. K. Jackson, '95, of Rutland, Vt.; auditor, Mr. W. C. Stead, '96, of Rome, N. Y.; assistant secretary, Dr. L. B. Morrison, '02, of Robert Maynard, '11, and Dr. J. A. Archambault, '01, of Burlington, were appointed to the committee, Dr. C. M. Ferrin, '65, of Essex Junction; Dr. F. K. Jackson and Dr. George H. Parmenter, '02, of Montpelier.

New England Alumni Associations of Baltimore Institutions.—About fifty members, from all parts of New England, attended the eighth annual joint meeting and banquet of the New England alumni associations of Baltimore Medical College and the University of Maryland, held at the Academy of Music, in Boston. Dr. Charles A. Glancy, of Providence, the retiring president, was toastmaster, and the speakers were Dr. Florence A. Sullivan, of Haverhill; Professor David Scott, of Baltimore Medical College; Mr. Henry Edwards, of the University of Maryland; Dr. I. E. Willard, of Saco, Me.; Dr. E. B. Goodall, of Haverhill; Dr. H. H. Sumner, of Lowell; Dr. F. F. Sprague, of Concord, N. H.; Dr. Roland J. Goss, of Wilder, Vt.; Dr. C. B. O'Rourke, of East Providence, R. I.; Dr. F. E. Smith, of Watertown; Mr. A. C. O'Reilly, of Hadley, Mass.; Dr. E. Conroy, of Andover. These officers were elected: President, Dr. E. C. Conroy, president; Dr. Harry W. Wood, of Brookline, vice-president; Dr. Charles S. Gilman, of Boston, secretary; Dr. J. C. Devlin, of Lynn, treasurer. Other vice-president's elected were: Dr. L. E. Willard, of Maine; Dr. F. F. Sprague, for New Hampshire; Dr. C. C. Waller, of Lyndonville, for Vermont; Dr. L. B. LeGro, of Haverhill; for Massachusetts; Dr. C. B. O'Rourke, for Rhode Island; and Dr. George N. Burroughs, for Connecticut.

National Association for the Study and Education of Exceptional Children.—At the annual meeting of this association, held in New York recently, a board of directors was appointed, whose membership includes the following: Honorary presidents, Dr. Charles W. Eliot, president emeritus of Harvard University; Dr. G. Stanley Hall, president of Clark University; Dr. Abraham Jacobi, of New York, Hon. William H. Taft, ex-president of the United States; Dr. Ray Lyman Wilbur, of San Francisco, president of the American Academy of Medicine; Dr. Maximilian P. E. Grossmann, of Plainfield, N. J., Dr. Ira S. Weld and Dr. A. M. E. Washburn, both of New York. The presidents of the state councils are also members of the board. It is formally resolved to organize medical, educational, and sociological advisory boards, a general committee, and a women's auxiliary committee. A vigorous campaign is to be started at once to affiliate with the association all organizations in which children are concerned in some phase of child welfare work. Dr. A. Emil Schmitt, of New York, is president of the association, and Dr. Maximilian P. E. Grossmann is educational director.

Civil Service Examinations.—Among the positions for which examinations will be held by the New York State Civil Service Commission on July, 1913, is that of medical superintendent of the Montgomery County Tuberculosis Hospital, at Amsterdam, N. Y.; salary $1,000 to $1,200 and maintenance. Candidates must be well educated physicians, graduated from a reputable medical college, with an experience of at least six years in the actual practice of medicine, including at least one year's actual experience in a hospital. Subjects of examination and relative weights: Questions relating to hospital management, doctrine, including duties of superintendents; organization on general medicine, surgery, and hygiene, and the treatment of tuberculosis, 3; education and experience, 4. In connection with the rating on the last subject, candidates must be graduates of a nurses' training school. Special credit will be given for actual experience as executive head of a hospital. Open to all citizens of the United States, preference in certification being given to residents of the State of New York. Another position for which an examination will be held, also this year, is that of trained nurse to State institutions, which is open to men and women; salary, $420 to $600 and maintenance. Candidates must be graduates of a nurses' training school registered by the State Education Department. In connection with the rating on the last subject, candidates must have received the diploma of the Commission after July 18, 1913, will be accepted.

Changes in the Faculty of the Harvard Medical School.—Many changes in the faculty of the Harvard Medical School have been announced, among them the most important being Mr. Henry B. Hall Nichols and Dr. Charles Allen Porter to be associate professors. Dr. Herman Morris Adler becomes an assistant professor of psychiatry. Dr. Hugh Cabot, an assistant professor of gynæcological surgery; Dr. David Cheever, assistant professor of surgical anatomy; Dr. Eugene Anthony Crockett, an assistant professor of otorrhage; Dr. Channing Frothingham, Jr., Dr. Thomas Ordway, Dr. William Henry Smith, instructors in medicine for three years. Dr. Alexander F. Edwards and Dr. Heber C. Ayers, instructor in anatomy, and Drs. Sherman and Frank have been reappointed. Dr. John Bapst Blake, to be assistant professor of surgery; Dr. Richard Clark Cabot, assistant professor of pathology; Dr. Horace Gilmore, to be assistant professor of obstetrics; Dr. Howard Augustus Lathrop, assistant professor of surgery; Dr. Richard Clarke Cabot, assistant professor of medicine; Dr. Franklin Spillman Newell, assistant professor of obstetrics; Dr. Paul Thorsdale, assistant professor of anatomy; Dr. F. E. Conroy, assistant professor of surgery; Dr. Samuel R. Peabody, assistant professor of pathology; Dr. John Warren, assistant professor of anatomy; Dr. Malcolm Storer, Dr. Howard Townsend Swain, Dr. Ernest Boyon Young, Dr. Robert Laurent DeNorimonde, Dr. Robert Montvalle Green, Dr. Henry Tallot Huston, Dr. Nathaniel Robert Mason, Dr. James Rockwell Torbert, instructors. Dr. Ralph Leavitt Reynolds receives the appointment of assistant professor in obstetrics and Dr. Richard Goodwin Wadsworth is made a fellow in surgery for next year. All of the appointments go into effect on September 15th.
The Question of Oxalic Acid Formation and Elimination in Man.—L. Lichtwitz and W. Thorner give the following conclusions: 1. In most patients with icterus the urine contains an increased amount of oxalic acid. 2. As the ductus choledochus grows more permeable the oxalic acid is decreased. 3. The escape of a certain amount of oxalic acid in the bile has been demonstrated by other investigators as well as themselves. 4. The ingestion of from two to five grammes of glycocoll produces no increase of oxalic acid in the urine. 5. Gelatin increases the formation of oxalic acid. 6. The observations of Wegrzynowski prove again the importance of intestinal flora in relation to the formation of oxalic acid. In Fürbringer’s patient the action of bacteria (Aspergillus niger) in causing its formation in the lungs is distinctly shown. 7. The ingestion of roasted partridge does not lead to an increased output of oxalic acid.

May Neosalvarsan Be Used for Outpatient Service?—A. Wolff and P. Mulzer sound a warning against the use of neosalvarsan in ambulatory patients. According to Lesser, some sixteen or eighteen such patients who had been treated with neosalvarsan have fallen unconscious in railroad stations, workrooms, hotels, and other places, and died a short time after. According to the authors’ and other investigators’ observations, neosalvarsan, even in small doses, produces much more toxic effects than the old salvarsan. The authors have abandoned the use of a remedy which they regard as so dangerous.

Action of Adrenalin on the Coronary Arteries.—F. Meyer, from experimenting on animals, finds that the administration of adrenalin produces remarkable acceleration of the coronary circulation, the result of increased blood pressure, from the heightened action of the heart. As shown also by other authors, adrenalin causes an increase in the calibre of the coronary vessels, as well as an increased flow of blood through them.

The Treatment of Tabetic Manifestations with Arsenical and Bacterial Preparations.—Döllken’s experience has shown that mercury salicylsarsenol (enesol) is a valuable remedy in tuberculous therapy. The lancinating pains diminished or were entirely relieved; there was gain in nutrition and strength; ataxia improved; also the crises were favorably influenced; but pupil and tendon reflexes never returned during treatment. On the other hand, the author also witnessed numerous relapses after from four to six months. Schaffer and Hudoevering have accomplished even better results with enesol. Aside from destructive processes in the spinal cord and posterior roots, there are found, during the entire process of tabes, subchronic, chronic, and other recurrent processes in the peripheral nerves and in other organs. Three kinds of remedies may produce therapeutic results: first, bactericides, if these can be brought into contact with the elements exciting tabes phenomena; second, bacterial products and remedies which have the ability to inhibit the toxines and render them harmless; third, albuminous, natrium, and like inorganic substances, the like inorganics force the organism to a powerful reaction under febrile conditions and hyperleucocytosis. The organs themselves may thus be excited to the making
of antibodies, as well as the phagocytic and leucocytic ferments in addition. Wagner has the credit of having first studied the systemic and favorable action of such agents as tuberculin on paralysis.

Arsenical Paralysis.—Obermiller concludes from his own observations and those of others that the unfavorable results which have been noted from salvarsan and neo-salvarsan are purely symptoms of arsenical poisoning, and that the cerebrospinal accidents which sometimes occur from their use represent only this, and therefore should be avoidable.

WIENER KLINISCHE WOCHENSCHRIFT.
May 1, 1913.

Treatment of Exophthalmic Goitre by Irradiation of the Ovaries with X Rays.—J. Mannenber reports ten cases of exophthalmic goitre in which he obtained improvement of all the symptoms except the goitre by irradiating the ovaries with the x rays. He thinks that the ovaries play some part in the clinical picture of this disease, it may be from the formation of some substance in the ovaries which acts upon the thyroid and modifies its functions in such a way that exophthalmic goitre is the result. The x rays dry up the source of this substance in the ovaries, and so allow the thyroid to resume its normal functions. It might be wise to supplement the radiotherapy with a course of thyroid treatment. Eight of the ten patients treated by him gained considerably in weight, in one the exophthalmos disappeared completely, and in half the cases there was more or less improvement. Subjectively, nearly all the patients feel quite well and are able to work. The ages of the women ranged from twenty-one to forty-two years. The number of exposures varied from three to fifteen.

A Case of Cyclic Paresis of the Oculomotorius.—Hans Lauber reports a curious case of this rare condition, met with in a six year old boy, in whom it had been noticed since he was six months old. The left eye was normal. The right eye could not be moved voluntarily except a little by the abducens and by the superior oblique, the upper lid hung down in incomplete ptosis, the pupil did not react to light, convergence, psychic, or sensory stimuli. Yet the muscles affected by this paresis of the oculomotorius made certain involuntary contractions, especially during sleep. The upper lid would suddenly rise, the eyeball would be adducted to the middle line, and the diameter of the pupil would change from four mm. to 1.5 to 2 mm. This condition would last for from fifteen to thirty seconds and then, with slight twitches, the lid would sink, the globe return to its abducted position, and the pupil dilate. After an interval of from thirty to ninety seconds the phenomenon would be repeated.

Arsenic Poisoning.—Erik Lindstroem tells of his personal experience and that of his son, eleven years old, the result of sleeping in two rooms that had just been painted. He occupied his room four months and then went on a vacation, during which time neuralgic pains developed, which were distressing, but subsided when he lay still. These pains lasted a month, and then subsided during the summer, but returned the next winter with great severity and became so bad that he could not use his right hand. An obstinate conjunctivitis developed in the boy, who grew pale and thin. Arsenic poisoning was suspected now for the first time, and arsenic was found in his urine, as well as in that of the other members of the family, and arsenic was found in large quantities in the oil paint on the walls of the rooms. It was also found that the poisoning was most severe in the rooms that had received the greatest number of coats of paint.

May 8, 1913.

Operative or Conservative Treatment of Stab Wounds of the Lungs.—Ernst von Kutscha reports four cases in which operative treatment was required and eight in which it was unnecessary. He holds that severe hemorrhage and collapse from pneumothorax justify operation. If the thorax is opened the opening should be made large enough to permit the wound in the lung to be readily sutured before any other measures are attempted.

Cancer of the Lungs.—Alfred Arinstein reports another case of cancer in the lungs in a miner in the Schneeberg district of Saxony. According to the statement made by Haerting and Hesse in 1878 and 1879, seventy-five per cent. of the deaths among these miners are caused by a lymphosarcoma of the bronchial glands, or an endothelial sarcoma. Arinstein finds that the diagnosis made in one third of all the cases admitted to the hospital from 1907 to 1911 was cancer of the lungs, and that this was given as the cause of death in forty-four per cent. of the death certificates. He was able to examine two cases post mortem, and found chronic pulmonary tuberculosis in one and careinoma of the lung with metastasis in the other. He is inclined to think that errors of diagnosis have been made, as autopsies are uncommon, and that tuberculosis has been responsible for many of the deaths.

May 15, 1913.

Anaphylactic Poisoning.—R. Kraus and P. Kirschbaum declare that we should be very careful how we call a poisoning anaphylactic, for their results show that the so-called anaphylatoxine produced in the test tube is not necessarily identical with the anaphylactic poison.

Typhoid Infection of the Biliary Passages with Aplasia of the Gallbladder.—Stefan Zarzycki reports the case of a woman, twenty-five years old, who proved to be a carrier of infection after recovery from an attack of typhoid fever. Operation to remove the gallbladder revealed its congenital absence. Experiment on a rabbit confirmed the clinically proved fact that the large biliary passages furnish a good nutritive bed for a permanent deposit of typhoid bacilli, even when the gallbladder is absent.

May 22, 1913.

The Benzol Treatment of Leucocytethmia.—Otto Alfred Roesler reports two cases in which great benefit seemed to be obtained from treatment with benzol, though final judgment cannot be passed upon the results as yet.

The Formation of Specific Agglutinins in Artificial Tissue Cultures.—P. Przygode finds that tissue of the spleen, exposed to the action of an emulsion of typhoid bacilli in a plasma culture, forms in the test tube specific agglutinines against these bacilli.
Inhibition of Inflammation.—Hans Januschke finds that the acute exudation in the inflammatory chemosis of the rabbit’s eye produced by oil of mustard may be prevented by medicamental or degenerative blunting of the sensory filaments of the trigeminus in the conjunctiva. The swelling of the conjunctiva caused by oil of mustard may also be greatly lessened or prevented by general narcosis, by the subcutaneous injection of such anesthetics and analgesics as morphine, antipyrine, sodium salicylate, or quinine, as well as by such sedatives as sodium bromide. The inhibition of the inflammatory exudation in the conjunctiva by narcotics takes place independently of narcosis of the central nervous system. The swelling may be restricted somewhat by the subcutaneous injection of salts of lime and of magnesium, and of epinephrin. Almost all the materials tested experimentally have been observed clinically to be able to act antiphlogistically in certain vascular regions and against certain inflammatory agents. In many forms of acute and chronic coryzas the internal administration of calcium lactate seems to be indicated.

Zentralblatt für Gynäkologie.

May 29, 1913.

The Technic of Cesarian Section.—Veit calls attention to the necessity of simplifying the technic as much as possible, in order that the comparatively inexperienced operator may get good results. Veit makes use of Frank’s transperitoneal method of opening the lower uterine segment. By stripping off and reflecting the peritoneum he has succeeded in quite a number of cases in extracting the baby extraperitoneally.

Inversion of the Uterus.—Rorize reports an interesting case of atony of the uterus complicated by placenta previa. In consequence of the extreme thinness of the wall (from 0.5 to one cm.), the uterus became inverted, and was extirpated by the operator. On account of the great loss of blood preceding the operation, the patient died shortly afterward.

A Case of Rupture of the Uterus Following the Use of Pituitrin.—Herz reports a case in which a twenty year old primipara was in labor for forty-eight hours, the pains not being at all marked. The patient was then given an injection of one c.c. of pituitrin. Within three or four minutes the pains began, and rapidly grew more and more severe. In the course of about twenty minutes they became tetanic, lasting from five to seven minutes. An hour after the injection there was a terrific tetanic contraction, causing the patient to cry out and then collapse. Somewhat later the child was born, and examination showed that the anterior portion of the cervix had been torn from the uterus wall (colporrhesis). At the end of fourteen days, when the last of the gauze packing was removed, it was found that the torn cervix had firmly united to the wall of the uterus. The author believes that pituitrin should be used with the greatest care during the early stages, when there is rigidity of the cervical opening.

May 29, 1913.

Perforation of the Uterus.—Maly presents briefly a case in which a physician undertook to cause an abortion on account of the critical condition of the patient, due to a cardiac lesion. The rigid cervix was being dilated by means of a blunt dilator when the instrument suddenly encountered no resistance. The abdomen was opened, blood removed, and a clean, sharp wound, 1.5 cm. long was found on the anterior wall of the cervical portion of the uterus. This was sewed up, and the abdomen closed, the patient making an uneventful recovery.

The Care of the Umbilical Cord.—After trying various methods, Nadory recommends the following: He ties the cord close to the skin with a silk ligature, cuts the ends short, and cuts the cord some one to 1.5 cm. above the ligature. The stump, as well as the umbilical ring, is thoroughly painted with iodine. After the infant’s bath the iodine is again used. In the course of from two to three days, as a rule, the stump comes off. This method has been employed in fifty cases with good results. In this way all danger of infection is avoided, and the small stump rapidly shrivels. No bleeding occurs, the ligature preventing it. Then, after the separation of the stump, no further treatment is needed, as there remains only a smooth, clean scar.

Delivery in a Case of Complete Paralysis of the Back and Lower Extremities.—Bogdano-witsch gives in detail an interesting case in which there was paralysis of the lower extremities of the back and of the upper extremities as well. Although there was this complete loss of muscular power, the uterus spontaneously contracted, and in the course of about three hours the baby was born. The mother died two days later from respiratory embarrassment. It is evident from this case that the motor functions of the uterine muscle are not dependent upon the spinal cord, but evidently upon the peripheral nerve centres that are localized in the uterus.

Centralblatt für allgemeine pathologie und pathologische anatomie.

May 31, 1913.

A Hypernephroma in a Frog.—Carl briefly reports the finding of such a tumor, one in which neither glycogen nor chromaffin cells could be demonstrated.

British medical journal.

June 7, 1913.

The Lachrymal Gland in Surgical Anesthesia.—L. T. Rutherford seems surprised that the activity of this gland in anesthesia should have escaped notice for so long a time. He has given its behavior careful study in a series of over two hundred cases, and lays down its responses to the different stages of anesthesia as follows: 1. In the first stage the activity of the gland varies according to the strength of the irritation in the nose, and, if no vapor reaches the cornea, the canthus may be dry. 2. With the onset of the stage of excitement the glands become very active, and pools of secretion appear in the inner canthi. 3. During the stage of surgical anesthesia the glands cease to secrete, and with increasing depth of anesthesia they do not resume activity, so that in overdose they remain dry. Therefore, the inner canthi may be wet or dry in the first stage, are filled, in the second, and, if the secre-
tion from the second stage is kept mopped up, the canthi remain dry after the inception of surgical anesthesia. The importance of these observations lies in the fact that, when the pupil begins to dilate during the administration of ether or chloroform, and secretion remains absent from the canthi, an overdose is being given, whereas, if secretion appears in the canthi, the stage of surgical anesthesia is passing off and more anesthetic is needed. Ruth-
erford believes that the observation of the canthi thus forms a very valuable aid to the estimation of the depth of anesthesia, and provides a very certain and early sign of an impending escape from anesthesia or of an overdose.

Sleeping Sickness and Big Game.—Warrington Yorke’s researches show that in Africa the continuous supply of trypanosomes virulent for man and the domestic animals is to be found in the big game, from thirty-five per cent. to fifty per cent. of all of the larger wild animals in nature being infected. From this source the several flies, more particularly the Glossina morsitans, derive their infection, which they then transmit to domestic animals or to man. The extermination of these flies is a practical impossibility, as shown by previous studies. Yorke therefore suggests that an experiment be made upon the extermination of the larger wild animals in a given area, or that from such an area all such animals be driven out. He believes that their absence would not only soon rid the region of the infected flies, but that even the uninfected flies would become very much diminished in numbers. Owing to the nature of trypanosomiasis, it seems wholly improbable that man and the domestic animals would propagate the infection for long.

LANCET.
June 21, 1913.

The Place of Climatology in Medicine.—William Gordon (lecture II) cites the elaborate statistics of Muteller, of Switzerland, for the years 1855 to 1895, and in addition many other similar, though less complete sets of figures brought forth since the days of Koch. These statistics are care-
fully analyzed by Gordon with reference to the effect of altitude alone upon the prevalence and the course of tuberculosis. He finds that altitude alone has no influence whatever on either factor. On the other hand, in the presence of prevalent rain bearing winds, increase in altitude brings about both greater frequency of the disease and a decidedly unfavorable effect upon the course, leading to a materially increased mortality rate. This is true only to a limited extent, however, the effect increasing from low lands with rise in altitude up to the point at which exposure to winds remains great, but the relative humidity falls. There is a zone at a medium altitude in which exposure and rainfall are greatest for any given region, and in this zone tuberculosis is at its worst, both as regards morbidity and mor-
tality rates. In conditions of shelter from rain bearing winds altitude has no effect on prevalence of the disease.

Tetragenus Septicemia.—John Byers’s and Thomas Houston’s patient was a boy of eleven years who had suffered for years from recurrent attacks marked by respiratory catarrh, bronchitis, bronchopneumonia, throat, nasal, and ear troubles, and, at times, abscesses and diarrhea. His last at-
tack began with nasopharyngeal catarrh and pain in the ears. After a short period of improvement he became feverish, had an attack of epistaxis, and bronchopneumonia and catarrhal involvement of both ears developed. His condition progressed unfavorably, and he was becoming moribund when the Micrococcus tetragenus was isolated from his throat, nose, ear, blood and urine. Though it was in mixed culture in the throat and nose, the sporic index lent confirmation to the belief that it was the prime cause of his infection. A pure autogenous vaccine of this organism was given, later being com-
bined with one of the pseudodiphtheria bacillus for a local ear infection. Speedy recovery was made, though the patient was believed to have been moribund when the first dose was given.

A New Spirocheta Found in Human Blood.—Helen Chambers was led by her histological investiga-
tions of the thyroid gland in exophthalmic goitre to believe that the changes in many of the glands were of the nature of inflammatory responses to some infecting agent. Upon this hypothesis she was further led to make a search for an organism of a protozoal order, as she was unable to find any sign of bacterial infection of the gland itself. In her studies she found an actively motile spirocheta in the serum which separated from blood drawn into a small pipette. The organism is from four to thirty microns in length, may be thick or extremely thin, its curves are being constantly obliterated by its motions, the ends are usually rounded, and some-
times the ends are swollen and look like spores. The spirochetes have been seen in process of divi-
sion, which takes place longitudinally. They can be stained with Leishman and Giemsa’s stain, when small, red, chromatin granules are often found at their ends, or sometimes occurring along their length. Other methods of staining can be used, but the best method of finding it is in the fresh serum, examined in the dark field. It has been possible to cultivate the spirocheta in blood drawn into broth, in blood alone (allowed to clot), and in blood drawn into molten agar. In each instance the organisms are to be found in the region of the red cells which are present. No successful subculture on artificial media has been made as yet. The organism is often very abundant in the blood drawn from a person to all appearances in full health. In forty-seven cases, including fifteen persons in health, Chambers has found the spirochete in all but three. She offers no suggestions as to its nature or significance.

INDIAN MEDICAL RECORD.
May, 1913.

Eucalyptus in the Treatment of Pulmonary Tuberculosis.—L. G. Pedigo has obtained good clinical results in pulmonary tuberculosis, as well as in ordinary colds, by the induction of a teaspoonful of a twenty-five per cent. eucalyptus ointment. The premises of the treatment are: Oil of eucalyptus is known to be inimical to bacterial and parasitic life: in whatever way this agent enters the circulation it will be eliminated chiefly through the lungs, the habitat of the tubercle bacillus in pulmonary tuberculosis. Essential oils, like the oil of euc-

lyptus, are irritating to the mucous membrane of the stomach; hence the oil cannot be adminis-
tered in this way. Given hypodermically, it is a local irri-
tant. It is very volatile, but to give it by vaporiza-
tion the patient needs to be subjected to an ex-
haustive vapor bath. It can, however, be introduced
into the circulation readily by incorporating it with
an oily base and rubbing it into the skin. It is de-
sirable to have a mixture that will remain firm at
ordinary temperatures, but will melt rapidly at the
temperature of the skin surface. and to have the
base one that will readily penetrate the skin. One
that he recommends for the colder months is as
follows:

<table>
<thead>
<tr>
<th>Substance</th>
<th>Quantity</th>
</tr>
</thead>
<tbody>
<tr>
<td>Olive oil</td>
<td>5ij</td>
</tr>
<tr>
<td>Benzoinated lard</td>
<td>3yj</td>
</tr>
<tr>
<td>Cacao butter</td>
<td>3iv</td>
</tr>
</tbody>
</table>

Cocoa nut oil also makes a good base for summer
use.

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.
June 28, 1915.

The Auscultatory Determination of Early Pathological Changes in the Lungs.—From a
study of this question Henry Sewell concludes that the earliest objective information of physical
changes in the lungs may be obtained through the use of auscultation, but this demands a analysis of
the sound into those vibrations due to resonance of the viscera and those of the chest wall, which latter
vibrations can be damped by pressure of an appro-
priate form of stethoscope. Vibrations transmitting
the whisper are confined almost wholly to the
viscera. The modification of the voice sounds by
which this quality becomes more amorphic and their
duration prolonged into an echo are the striking
characters which, when accentuated by stethoscopic
pressure, indicate pathological changes in the
viscera. The character and distribution of vocal
signs over the normal chest are sufficiently constant,
so that a topographic study of the chest by auscul-
tation may definitely suggest, through recognition
of slight abnormalities, the intensity and distribu-
tion of morbid intrapulmonary changes, which may
be too slight to be revealed by any other method.

MEDICAL RECORD.
June 28, 1915.

Dietetic Habit and Gastric Function.—Charles
S. Fischer states that while the question, What
shall I eat? when put to gastrologists, should be
answered with facility, it is one of the most difficult
to reply to promptly, in any given case. Notwith-
standing the progress made in the physiology of the
digestive processes during the past generation, not
one particular dietetic scheme has been evolved
which will meet the needs of the average run of
ordinary gastric disturbances. Except in the very
small proportion of abnormal functions, due to
direct abuse of the digestive organs, most vagaries
of gastric secretion represent, in the individuals
possessing them, indications of constitutional taint,
either metabolic, evoluzional, or temperamental, and
the secret of successful dietetic management of most
dyspepsias consists in methodically meeting these
conditions and adapting the food supply thereto. In
most cases the food intake, in both quantity and
quality, is adequate for the individual. Its distribu-
tion is wrong. In a general way the greater the
psychic strain, the more general should be the food
distribution, while he whose labor is entirely physi-
cal can endure longer intervals between meals as
the exhaustion is more gradual, more cumulative.
The exhaustion attendant upon mental effort is ir-
regular, increasing and diminishing according to
conditions, at various periods of the day, and there-
fore more frequent support is required, the response
being more rapid. The relief afforded depends not
so much on the nutrition involved, as on the relaxa-
tion from the overtension which frequent feeding
induces, under which the patient is laboring. In
the treatment of the common mixed forms of gas-
tric indigestion it has been demonstrated that a
simple, nonirritating, rationally conceived mixed
diet, distributed in such quantity and at such in-
tervals as to meet the requirements of general
energy disbursement and local muscular activity,
will accomplish the desired results in most cases,
irrespective of ordinary local conditions of acidity
or motility, and without the need of scientific gastric
analysis.

Some Remarks on Bronchial or True Asthma.
—Harold De Wolf describes asthma as paroxysmal
dyspnea, largely of the expiratory type, of more or
less sudden onset, and variable though short dura-
tion, which will at once exclude the so called asth-
omatic conditions developing in late cardiac and
renal disease, and confine us to true or bronchial
asthma with its allies—hay fever, rose cold, par-
oxysmal sneezing, and spasmodic bronchitis of
children, all having a common basis in patients of
the so called nervous or neurotic type, all being of
a paroxysmal nature, with sudden onset, and a
tendency to recurrence at more or less definite in-
tervals, and none in itself fatal, although any may
lead to a fatal issue. The disease is twice as fre-
quently in the male as in the female. While hay
fever and rose cold have a specific time of the year
to appear, asthma itself is more frequent in the fall
and spring, appearing frequently in family groups.
The prognosis in early life, before the nervous
system has acquired the habit, is good, it being
often possible to train the little patient and entirely
cure the condition. Later in life the hope of per-
manent relief is remote. Prophylactic treatment
includes good, wholesome food, abundant fresh air,
proper bathing and exercise, care of the bowels, and
prompt attention to any abnormal condition of the
nose and throat. In treating the attack nothing
given has given as good results to the writer as morphine
hypodermatically and amyl nitrite by inhalation; if
morphine is alone available, give enough and do
not "putter around with minimal dosage." Chloro-
form is recommended, but its effects are too transi-
tory. Adrenalin chloride has never given good
results in the writer's hands. Extreme exhaustion
or threatened collapse will be relieved by a cup of
strong coffee: strychnine, caffeine, camphor are
useful stimulants. Belladonna or stramonium cigarettes
will relieve a mild attack. Between attacks the
treatment is climatic, hygienic, and medicinal.
Autotherapy, as elaborated by Duncan (see this
JOURNAL, vol. xcv. Nos. 24 and 25), promises
results far and away beyond any the writer knows.
Nephritic Overtension; Clinical and Experimental Studies.—Theodore C. Janeway calls attention to the labor expended in the study of the supraparenal glands, of which the net result is the solid, well grounded fact that the supraparenal glands, or at least their medullary portions, prepare a substance, epinephrin, which, introduced into the circulation, produces a rise in the systemic arterial pressure unequalled in intensity by any other known substance. While this rise is extremely transient the continuous, steady introduction of epinephrin is capable of maintaining a state of overtension as long as the introduction is continued. Coincident with this rise in blood pressure is a reduction in the volume of the extremities and of many organs, due to local vasoconstriction, so that the actual blood flow through them is diminished. Epinephrin, however, dilates the coronary artery, inhibits peristalsis, and abolishes intestinal tonus. Epinephrin also relaxes the bronchi when in a state of spasm. It is probable that during life epinephrin is constantly entering the general circulation from the adrenals, but except in the blood of the adrenal veins, epinephrin has never been positively identified in the general circulation of the normal animal or man. In renal disease the symptoms of overtension, the writer believes, can arise in three ways: Through a purely quantitative reduction of kidney substance below the factor of safety; in connection with the unknown intoxication called uremia, which causes disturbances of the central nervous system; in primary irritability of the vasoconstricting mechanism from unknown, probably extrarenal, causes, which lead eventually to arteriolar sclerosis. The vascular poisons back of these types of overtensive disease are unknown. Lead poison certainly does, and excessive stimulation of the central vasomotor mechanism must play some part in this action. The first and second types of overtension may at any time be superimposed upon the third. While the second, the uremic type, must be considered dangerous in itself, overtension in the arteriosclerotic or atherosclerotic kidney should be regarded as a compensatory effort to be interfered with only when danger threatens, either of cardiac failure or of cerebral hemorrhage.

The Circulation in the Arm of Man.—Albion W. Hewlett finds that, in studying the local circulation in the arm of man, local conditions must always be considered. The tachogram, the volume pulse, and the finer waves of the radial pulse depend in large part upon the condition of the larger arteries. The blood flow and the temperature of the part depend largely upon the condition of the finer arterioles. The color of the part depends partly upon the condition of the cutaneous capillaries and venules and partly upon the local flow. Changes in any of these cannot be referred entirely to changes in the heart action. Thermic effects produce many changes in the local circulation, and the function of the skin as a physical means of heat regulation must not be lost sight of in this connection. Chilliness or warmth, whether from external temperature or from fever, profoundly influence the peripheral circulation in an extremity. General and local warmth are the most efficient means we have to increase the circulation in an extremity. The effect of drugs is insignificant in comparison with these thermic measures.

An Instance of Premature Beats Arising in the Auriculoventricular Bundle of a Young Child.—This case is reported by Thomas Lewis and Herbert W. Allen, and concerns a child, aged four and a half years. The percussion outline of the heart is normal, the sounds everywhere clear, but the normal rhythm is interrupted by moderately frequent premature contractions, each of which is accompanied by two heart sounds. No abnormalities found in the other organs. The point of origin of the beats is probably to be located in the main stem of the auriculoventricular bundle.

Combined Tuberculosis and Carcinoma of the Stomach, with a Report of a Case upon Which a Partial Gastrectomy was Performed.—Henry H. Lyle observes that the present consensus regarding the coexistence of tuberculous inflammation and cancer coincides with the views advanced by Bayle in 1810, notwithstanding the claim of Rokitansky in 1830, that there was a mutual antagonism between cancer and tuberculosis. Cancer and tuberculosis can occur in the same individual and in the same organ, as demonstrated by six cases collected by the writer, one of which was discovered by operation; the remaining five by autopsy. The interesting point in the first case, beside the association of these two supposedly antagonistic lesions, is their sequence. From the clinical and pathological evidence the original lesion of the stomach was probably a tuberculous ulcer of the pylorus, secondary to a possible old lesion of the right apex. From this tuberculosis ulcer a diffuse carcinoma developed.

The Control of Rabies.—Henry Albert gives the statistics bearing upon the prevalence of rabies in the world at present, the number of persons bitten by rabid dogs, the prevalence of rabies in the United States, and a comparison of the distribution of the disease in this country in 1908 and 1911. The methods for the control or eradication of rabies considered are, immediate local treatment. Pasteur antirabic treatment, accurate diagnosis, and regulations aiming at the control of rabies in dogs and other lower animals (the licensing, muzzling, detention, destruction, and quarantine of affected dogs). To effect extermination of the disease the writer advocates the better instruction of the public, that they should realize that rabies is prevalent in most countries of the world, and that in parts of the United States it is on the increase; that it is possible to exterminate the disease by adopting certain regulations concerning dogs; that the muzzling of dogs is not a hardship to the animal, and that all the stray or ownerless dogs should be killed; that eradication is worth while because of the loss to live stock; that efforts at eradication are justified by the loss of human life and the worry incident to a dog bite.
RELATION OF Gastric AND DuodenAL Ulcer TO Vascular Lesions.—W. Ophils asserts that the commonest type of gastric or duodenal ulcer, at least in material obtained by necropsy, is the artiosclerotic ulcer in persons over thirty years of age. He presents a table in which details are given concerning eighteen such cases, found among about 1,500 necropsies. There is a second class of gastric or duodenal ulcer, in the young, which is probably due to local endarteritis (four cases). One also occasionally observes acute embolic or thrombotic ulcers (one case).

Effect of Change of Posture on Arterial and Venous Pressures.—J. H. Barach and W. L. Marks give the results of investigations on forty-eight students. The subjects were placed on a table with a movable top, and the experiments so conducted that the effects of change of posture on the pressures were not vitiated by any muscular exertion of those under test. Change from the erect to the horizontal posture was found to cause an increase in the maximum pressure, a decrease in the minimum pressure, and an increase in the pulse pressure. Upon return to the erect position, after five minutes, the reverse pressure changes took place. The venous pressure was lowered by change of posture from the erect to the horizontal. In “poor muscular cases” there was a tendency to reversal of the pressure curves, change from erect to horizontal position causing in over one half the cases a decrease of maximum and an increase of minimum pressure.

Budding and Other Forms in Trophozoites of Entameba Tetragnata.—S. T. Darling concludes that the descriptions of the life cycle of Entaméba histolytica by Schaudinn and Craig are in all likelihood those of a spurious species, having resulted from observations of pathological changes in serié races of Entaméba tetragnata.

Therapeutic Value of Theobromine Sodium Salicylate in Acute Experimental Nephritis.—H. A. Christian and J. P. O'Hare produced acute nephritis with uranium nitrate in a large series of rabbits and gave diuretin in amounts varying from large doses to doses equivalent to one gramme dose in the human subject. The results supported the view that in severe acute nephritis a diuretic drug such as diuretin is contraindicated, as in the experiments the drug shortened the life of the animals. On the other hand, of the survivors three fourths had received diuretin. This rather indicates that in less severe cases diuretin may be beneficial, and so justifies the cautious use of the drug in moderately severe cases of acute nephritis.

Infantilism and Pituitary Neoplasm.—E. J. Mullally reports a case presenting the following features: Marked underdevelopment of the skeleton and organs; “infantile” mental state; brain tumor symptoms; feminine contour of body, and slight myxedema. The patient weighed seventy pounds and appeared twelve years of age, though actually twenty-six. Acetumoria, diaceturia, and fever preceded death. The necropsy revealed, among other conditions: Cystic degeneration of the pituitary, with complete disappearance of the posterior lobe and only a few degenerated cells representing the anterior lobe; free communication through the pituitary stalk with the third ventricle; neoplasm of the choroid plexus extending into the pituitary; excessive colloid material in the thyroid; vacuolation of the fasciculate layer of the adrenals, and underdevelopment of the testes.

Determination of the Diastolic Pressure in Aortic Regurgitation.—A. E. Taussig and J. E. Cook conclude that with the auscultatory method of sphygmomonometer observation the beginning of the fourth phase in the arterial sound—that is, the point at which it becomes dull—marks the diastolic pressure. Since this point can readily be made out in aortic regurgitation, the auscultatory method is as applicable to this condition as to any other. The persistent arterial sound is not pathognomonic of aortic regurgitation, being often absent in this disease and occasionally present in other conditions. In cases with very low blood pressure, in those with marked dyspnea, and in Cheyne-Stokes breathing, the auscultatory method is especially valuable.

The Use of Vaccines in Eye Infections.—James Garfield Dwyer published in 1910 the results he had obtained from vaccine treatment in a series of infections of the eye, ear, nose, and throat; since then the series has grown to cover 300, and time has strengthened his conclusion that in vaccines, properly used, we have an agent that has no equal in certain cases. Of twenty-seven patients with recurrent hordeola, twenty-four have been free from the attacks since treatment, one did not seem to improve at all, and two are still under treatment. The Staphylococcus aureus was found in the majority; some contained the albus, a few the citreus. Autogenous vaccines were used in all. The series was limited to cases that had lasted for years, and the recurring hordeola appeared to be small local foci of suppuration, due to infection with certain organisms in persons whose resisting power was below normal. One striking result is that the patients feel better generally after the treatment. Other infections treated were the tubercle bacillus, twelve; gonococcus, six; pneumococcus, three; streptococcus, four; staphylococcus, seven; Friedländer’s bacillus, one; Morax-Axenfeld, two; xerosis, two; Micrococcus catharalis, one. The infections with the tubercle bacillus comprised phlyctenular conjunctivitis and keratitis, five; iritis, one; choroiditis, one; keratitis, three, episcleritis, two. The results of treatment with tuberculin were excellent in all these cases, and Dwyer thinks that tuberculous eye affections are ideal ones for tuberculin treatment. The results from the use of vaccines in the other infections were equally gratifying, even including the three infections with the pneumococcus.

THE TREATMENT OF TYPHOID FEVER.—From a careful study of this question O. H. Brown concludes that the ideal prophylactic treatment of typhoid is the proper disposal of human excreta. The inoculation of dead typhoid bacilli, however, is of very great value in preventing typhoid, and should
Experimental Streptococcic Arthritis in Rabbits.—Jackson, in experiments made with streptococci from a milk epidemic of sore throat in Chicago, was able to produce inflammatory conditions in the joints of seventeen rabbits. These were studied at periods varying from two hours to four months, and the differences present were only such as were consistent with the varying phases of a single inflammatory process. Also there were no striking differences in the reactions produced by the various kinds of streptococci employed.

Some Experiments Bearing upon Droplet Infection in Diphtheria.—Teague undertook to determine whether diphtheria patients in coughing and talking emit diphtheria bacilli frequently or only rarely, and whether in large or in small numbers. He found that in both talking and coughing, such patients frequently emit droplets containing viable diphtheria bacilli, but that such droplets are usually in small number. It was also noted that the bacteria in the suspended droplets would remain alive much longer in cool or cold temperatures than in warm.

Epidemiological Diagnosis and Management of Typhoid Fever.—Hunt gives an interesting report of an epidemic of typhoid fever and the means employed in determining the source of the infection. It was also the first time (so far recorded) of an antityphoid vaccine being generally used during the height of an epidemic. Taking the number of secondary cases as a measure of the preventive work done, there were in this instance but four, and three of these were nurses.

The Meioestagmin and Epiphanin Reactions in the Diagnosis of Carcinoma.—The first of these reactions is dependent upon variations in the surface tension of the serum, while the epiphanin reactions depends in part on an acceleration of the rate of diffusion in a solution when antigen and its specific antibody are introduced. Burmeister found that a decidedly negative meioestagmin reaction is of more value than a positive one, and may be considered of some weight in ruling out carcinoma. A moderately or even strongly positive reaction is not necessarily indicative of malignant tumor. The epiphanin reaction he considers valueless in the diagnosis of malignant tumors.

Study of an Outbreak of Septic Sore Throat Occurring in Concord, N. H., in January, 1912.—Mann reports an investigation made of an epidemic in which probably 1,000 persons were attacked by the disease. The milk was suspected, but could not be proved to be the source of infection. Further inquiry, however, elicited the fact that the cases occurred only among those who used cream from a certain source. It was shown that the milk became infected through the handling by persons suffering with the disease, and the cream when separated from the milk retained the infecting organisms. Mann holds that it is not safe to use market milk in the raw state, and that efficient pasteurization should be insisted upon where vending is engaged in.
Concerning Secondary Infection in Pulmonary Tuberculosis.—Avery and Lyall first call attention to the proper interpretation of the terms "mixed" and "secondary" infection; the first referring to the simultaneous invasion of more than one species of pathogenic bacteria through the same portal of entry. The second indicates the entrance of infectious microorganisms at intervals following the implantation of the primary species. In regard to the lesions in tuberculosis, it is at present generally held that the combined action of other pathogenic organisms may aggravate and accelerate the ulcerative processes, and thus exert a grave influence on the course and prognosis of the disease. In an attempt to determine the exact pathological significance of secondary infection, the authors made a bacteriological study of the blood with reference to organisms other than the tubercle bacillus in one hundred and fifteen cases of pulmonary tuberculosis, in various stages of the disease, and in five cases of bronchiectasis. The bacteriology of the sputum of twenty of these patients was studied at the time of the blood culture, to correlate, if possible, the findings of the one with the other, and of both with the clinical course of the disease. The examination of the sputum showed results that differed but little from those reported in a series of cases of nontuberculous diseases of the respiratory tract: and from the findings it was difficult to draw inferences concerning their clinical significance. In regard to the blood cultures, in no case was the presence of a secondary bacteriemia demonstrated.

Further Studies upon the Leprosy Bacillus. Its Cultivation and Differentiation from Other Acid Fast Species.—Duval and Harris give an interesting review of this subject and demonstrate that the acid fast bacillus known in the human leprous lesion as the Hansen organism can be cultivated in vitro under special nutritive conditions. The initial multiplication away from the tissues of the host occurs in the presence of the split products of animal protein, the amino acids, and under no other conditions. The authors have found also that the experimentally induced leprosy affords no reliable means of differentiating acid fast species other than the tubercle family, since the lesion in all instances has the same general gross appearance.

The Experimental Production of Pernicious Anemia in Rabbits.—As it has been shown that the hemolytic substance of the head of the Dibo-thirocephalus labus is oleic acid, Adler sought to determine whether the introduction of a hemolytic fat into the digestive tract would produce an anemia in a rabbit. In each case, at some period of the experiment, a severe form of anemia appeared as a blood crisis. Hemoglobin from forty to fifty per cent., red blood cells about four millions, polychromatosis and anisocytosis, polychromatophilia, achromia, stippling, and the presence of normoblasts and occasional megaloblasts. Inasmuch as the hemolytic substance is a fat, it is not capable of true solution in the body fluid; the effect is not a uniformly diffused one, but is dependent upon the meeting of a part of the hemolytic fat with a red cell. The anemia produced is, therefore, probably due to a de-

STRUCTION OF red cells in the blood vessels, as the bone marrow showed nothing of note.

MONTHLY CYCLOPEDIA AND MEDICAL BULLETIN.

Unrecognized Pulmonary Lesions in Cases of Suspected Chronic Pleurisy.—C. M. Montgomery is convinced that mistakes of this nature occur more frequently than is generally recognized, and emphasizes the necessity of always suspecting a pulmonary lesion when one meets with signs suggesting fibroid changes in the pleura. This is supported by autopsy findings. Sometimes, though, a diagnosis of tuberculosis is made, the abnormal findings over most of the affected area (i.e., elsewhere than at the apices) are attributed to a thickened or obliterated pleura, to the neglect of an extensive, even if scattered, infiltration of the lung. The most important help in differentiating between a fibroid lung and a simple thickened pleura may be marked deformity and visceral displacement. Typical signs of consolidation, if present, will indicate lung involvement, and sometimes râles are of great assistance, but often a thorough knowledge of the history and symptoms is required to establish the diagnosis. In cases of pulmonary tuberculosis two signs in particular are apt to be neglected, except when occurring at the apices, viz., weakening of the respiratory murmur and râles. The importance of these signs is as great if they are distributed over a large circumscribed area as if over a small one. Diminished respiratory movement on one side is also a valuable sign.

Prevention of Bubonic Plague.—V. J. P. Jour- dan asserts that ship fumigation is often carried out too superficially. The only evident effect of five successive fumigations which he witnessed was the death of one rat. The rodents appeared as numerous after as before the fumigations. Only the cabin, crew's quarters and hold had been dealt with. The coal bunkers, fire and engine rooms, chain lockers, and other storerooms, as well as the bilges, should also be fumigated. Two or more bilgeboards should be removed from each side of every hold, and at least two sulphur pots be placed in the most suitable bilges. Then a number of pots should be placed on the floor of each hold, and when all of these have been ignited the hold tightly covered.

NEW ORLEANS MEDICAL AND SURGICAL JOURNAL.

General Paresis.—A plea for more thorough prophylaxis in this disease is made by Henry Das- pit because of our inability to attack paresis with any success, owing to the fact that symptoms of the disease are not in evidence until irreparable, cerebral atrophy having taken place. Though the diagnosis is usually early cut and may usually be made before the mental picture is complete, this early diagnosis does not help us. The usual tonic or mixed treatment, with incomplete courses of in- juction, is inadequate, no matter how long em- ployed, for it has been proved that organisms be- come tolerant in culture to the presence of weak solutions of mercuric chloride, etc. The writer beli- eves, also, that the pale spirochete grows in a
system where the mercurials are gradually introduced, and even though finally pushed to the point of tolerance. When the disease is observed some years after the initial lesion the usual procedure is to give a short course actively and then put the patient on mixed treatment or potassium iodide alone, which in neither case will keep a reaction negative for any length of time after ceasing treatment. As a rule, whether parapthisis of the nervous system or any other demonstration, the idea should be that whenever there is a positive Wassermann reaction, clinically supported, there is an active syphilis, and except in cases of frank paresis, the case should be energetically treated for the three year period, irrespective of how recent or remote the initial lesion may have been. In positive reactions, even when clinically negative, the therapeutic test will decide the advisability of long attention. Tissue changes will not be cleared up, but the further progress of the disease will be arrested. The writer advises the use of salvarsan (not one dose, but several), followed by intensive treatment for a period of three years. By intensive he means the abrupt saturation of the patient with mercury, and by any of the various means at command.

Epilepsy: Its Cause and Treatment.—H. L. Fougerousse avers that in spite of extensive investigations by the foremost scientists, equipped with the latest instruments and appliances, practically nothing has been learned as to the real cause of epilepsy. No uniform anatomical findings applicable to all types have yet been demonstrated. Because of the lack of this definite knowledge of the morbid anatomy, pathology, and etiology applicable to all forms of this disease, experiment and empiricism stamp all efforts at treatment. There is no specific, and none in sight. The most useful treatment, prophylactic in results, is the dietetic, and consists of the use of easily digestible, simple foods in reasonable variety and never in excessive quantity. This with moderate exercise, fresh air, and a simple life, is the best suggested. Surgical aid is seldom sought and is beneficial only in the reflex types of the disease.

Polioyelitis.—O. M. Patterson relates his experience with poliomyelitis or infantile paralysis as health officer for the parish of Morehouse during the year 1911. He concludes from the study of seventeen reported cases that it is a communicable disease in which strict quarantine and isolation are very important and useful. The period of incubation in these cases was from three to eight days. Those who visit the sick are the carriers of the disease, and prophylactic measures offer the most hope, as a satisfactory treatment cannot be offered. Children over twelve years of age were not attacked; nearly all the cases were from two to six years old. The disease prevails and spreads more rapidly during the warm, dusty weather. Most of the cases occurred in April, May, and June.

OPHTHALMIC RECORD.

May, 1913.

The Intracapsular Operation for Cataract after the Method of Professor Stancleanu, of Bucharest.—W. Likely Simpson describes this operation in detail. The incision in the cornea is a trible larger than the ordinary and made with a small conjunctival flap. An ordinary iridectomy is made. The anterior capsule is then grasped with the most prominent portion of the curve of a pair of forceps with no teeth, with which movements are made from side to side so as to rupture the zonule. After this has been done the forceps is removed and the cataract extracted by pressure with a spoon over the cornea, a little below its centre, with slight counter pressure above the wound.

Letters to the Editor.

FRIEDMANN'S ANTITUBERCULIN SERUM.

New York, July 8, 1913.

To the Editor:

In my statement of May 26th, addressed to the medical and lay press and setting forth the conditions on which I had accepted the direction of the Friedmann Institute of New York, I laid much stress on the fact that my chief and only desire is to remain in New York, furnished with all the data at my ready command; after which I would communicate to the medical profession the results obtained by the use of the Friedmann vaccine, whether those results were good, indifferent, or bad. I realized how enormous a task I was assuming. My work appeared to me in the light of a public duty; I felt that sooner or later my colleagues and the public would come to recognize the absolute sincerity of my purpose.

My own observations had led me to conclude that the Friedmann vaccine was worthy of a trial that is, of a prolonged trial. Since they my convictions have only become deeper.

My most serious objection was to the secrecy observed in regard to the vaccine. I had come to my own conclusions when I read that it contained live cells, and when, later on, Dr. Friedmann explained to me his method of preparation I found that I had been correct in my deductions; I felt that he was working along the right path, for the results obtained in bacteriotherapy from the introduction of live germs into the organisms are much more satisfactory than the results from the use of dead germs or bacterial extracts. In the Pasteur treatment, for instance, we inject an emulsion of live germs, avirulent for man when properly filtered; and when, however, not knowing the composition of Friedmann's vaccine, naturally showed itself averse to using it. On the other hand, Friedmann held, not without reason, that it would be unsafe to release all the data concerning his vaccine until he had placed it in the hands of every one who wished to administer it had made themselves thoroughly familiar with its use. The correctness of his contention was evident, and I could not at the time raise any strong objection to it. But now I have concluded that the medical profession is entitled to know that the vaccine is simply a homogenous emulsion of live, avirulent tubercle bacilli in plain sterile distilled water. The germ was isolated several years ago from a tuftle, and the culture has been maintained since that time by transplantation artificial culture media, according to the usual procedure.

Before long, full particulars concerning the culture and preparation of the emulsion will be made public, when sufficient time has elapsed to demonstrate the correctness of the present mode of operation. In the meantime I shall welcome any colleague who desires to familiarize himself with the administration of the vaccine, that he may use it personally on his own patients. I wish it distinctly understood that I have never claimed the efficacy of the treatment. In a disease like tuberculosis it would be most unscientific to draw any conclusion as to the value of a certain treatment at the end of two or three months. I can only say that I have now observed over 100 cases and that, in many of them, I have noted beneficial results, such as, according to my experience, have not been obtained in the same length of time, with any other known method of treatment.

Finally, I have not observed one case in which the judicious administration of this treatment had not a manner harmful to the patient. GEORGE GIBRER R. RAMBAUD, M. D.
Proceedings of Societies.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Special Queens Borough Meeting, held at Jamaica, April 7, 1913.

Dr. L. Howard Moss in the Chair.

Report of a Case of Perforating Ulcer of the Stomach—Presentation of the Patient.—Dr. Albert L. Voltz, of Queens, presented a male patient, twenty-six years old, with the following history: For the past two years he had been subject to eructations of gas, accompanied with the frequent passage of flatus. He had been subject to intermittent pain, and at no time was there any hematemesis. On February 22, 1913, he spent the night carousing, indulging freely in drinking and inordinately in crabmeat salad. On awaking the next day, at 3 p. m., he attacked heartily and fast and drank some highballs. At 6 p. m. he was seized with an attack of severe colicky pain in the epigastric region, which was somewhat relieved after vomiting of some mucus. Pulse 80; temperature 98.6° F. Doctor Voltz noted no particular tenderness or rigidity of the abdomen, although there was a slight firmness in the region of the stomach. He administered morphia hypodermically and ordered castor oil and 2 grs. of calomel in divided doses. He was summoned again at 2 a.m. on the 24th, and found the pain unchanged. He was advised an emetic, but it was ordered as there was no vomiting. As the bowels had not moved, he gave an enema containing a drachm of turpentine. The pulse was now 88, but there was no increase in temperature. Noting tenderness and rigidity along the whole right rectus muscle, he made a diagnosis of appendicitis and advised operation. This was refused, however, and he gave another hypodermic of morphia. At 6:30 a.m. he was again called, and he then found the patient sweating, and the abdomen had been enema of 994.6° F. and the abdominal rigidity was intense. After consultation with Dr. L. H. Moss, the patient was removed to the Jamaica Hospital, where at 9:30 a.m. laparotomy was performed; the incision being made over McBurney's point. As soon as the peritoneum was opened, several ounces of yellowish fluid escaped; suggesting a ruptured gallbladder. The appendix, which was found much thickened from chronic inflammation and markedly congested, was not appendicectomy, and the gallbladder had been enema of 904° F., and the abdominal rigidity was intense. Another incision was then made, but the gallbladder was found to be apparently normal. Considerable quantities of the yellowish fluid continued to pour out, and on further search for the leakage it was discovered that the pylorus, near the pylorus, had been perforated by a clean-cut ulcer, 1½ inches in diameter, with perfectly smooth edges. A pursestring silk suture surrounding it was passed about ⅛ inch from the border of the ulcer, tied, and buried in the gastric wall by means of Lambert silk sutures passed through the peritoneal coat. The peritoneum having been thoroughly washed with normal saline solution, a fenestrated rubber tube was placed behind the stomach, along the lesser curvature, and the wound closed about the tube. The patient was then put to bed in the Fowler position, and a Murphy drip started. The operations consumed about two and three quarter hours. There was more or less shock and the prognosis looked grave. Pulse 124; respirations 28. On the second day the temperature was 101° F., and the respirations rose to 30, though the pulse rate remained the same. After that, however, the patient made an uneventful and rapid recovery. In this case, Doctor Voltz said, it was noticeable that the patient did not go into collapse, that vomiting was absent except at the beginning of the attack, when a small amount of mucus was thrown up, and that, although the peritoneal cavity was bathed with the stomach-and-duodenal contents bathed the whole right side of the peritoneum, general peritonitis did not occur and the local peritonitis was only moderate in amount. The maximum temperature was 101° F. The rapidity of respiration he thought might possibly be accounted for by the proximity of the scant cuticular case to the diaphragm.

Report of a Case of Twin Pregnancy, Uterine and Tubal Combined.—Dr. C. O. Stumpf, of Queens, re-
with loosely fitting blades, used chiefly as a guide and to prevent recession; care being taken not to pull too suddenly or vigorously, in order to avoid too precipitate delivery and an unnecessary laceration of the perineum; (6) the judicious combination of two or more of these manoeuvres as required by the existing conditions. Having referred to the methods employed in delayed labor among uncivilized nations, as described by Engelmann, Doctor Gallant said there could be no doubt that the squatting posture was the most natural for the female. For the American woman, however, it had its advantages in accelerating the passage of the head through the pelvis. It was therefore to be regretted that the old fashioned obstetric chair, which in former times was used by the natives from both hemispheres, had been abandoned among Anglo-Saxon peoples. The great practical value of compressing the lower abdomen on the thighs, with the woman in the squatting or squatting posture, had been clearly demonstrated in a case he saw in consultation with Doctor Moss. The pains were frequent and of good force, but, although the membranes had been ruptured artificially, there had been no progress made for a long time, when the patient insisted on rising to have her bowels moved. A pall with a wooden seat was brought, on which she lay down, straining vigorously, and delivery followed so promptly that a seven and a half pound baby was barely saved from drowning in the pail. The change to a low sitting posture, in which she leaned forward with her elbows on her knees, accomplished the necessary flexion of the head, and the small child was precipitated through the comparatively roomy pelvis.

The advantages to be gained by early diagnosis of the unflexed head, and appropriate measures for promptly assisting Nature, was shown in the case of Mrs. K., who had been delivered in three confinements. She had previously had one child, and when this was born the labor was very slow and prolonged. At the time he first attended her she was a frail, slender woman, five feet and two inches tall, weighing one hundred and thirty-two pounds. The first stage of labor lasted five hours. The head was found in the R. O. A. position, and the os externum dilated and dilatable. The protruding membranes were ruptured with a knitting needle, and the head, waddling above the pelvic rim, was tilted anteriorly and flexed inwardly, the forehead inclined toward the fundus. It then readily entered the inlet during a pain, and the edematous anterior lip was pushed upward behind the symphyses. The pains were forceful, and at the end of the fourth contraction, twenty minutes after the rupture of the membranes, the head came rapidly down into the pelvis, and was guided through the vulva. The entire time occupied by the labor was but three hours and forty minutes.

When he attended her for the third time labor commenced at 1 p. m. and terminated at 9:15 p. m. The os externum being dilatable, he ruptured the membranes and repeated the procedures resorted to in the previous labor; and with the same successful result. External pressure on the fundus uteri and the breech of the fetus was avoided, combined with internal manipulation, to further flexion of the head and trunk, and thus help the occupant to engage during the pain, as well as prevent it from disengaging when the pain ceased. These deliveries, he said, illustrated in a striking way the present day idea in obstetrics, that by judiciously interposing his aid at a proper time we can reduce the hours of labor the workingman’s limit of eight hours, or even less; and this, frequently, without the use of the forceps. He did not hesitate to apply the former for this purpose, if necessary, for a like occasion. In other instances the forceps might be resorted to, to avoid more serious difficulties, as in a case he had attended where the head lay occiput anterior, transverse, with the forehead lowest. In response to upward pressure on the fundus, through the coiled thumbs of the operator downward into the left inlet. The pains being ineffectual and the advance very slow (although the membranes had been ruptured), and the patient being extremely excited, chloroform was administered to the obstetric degree, and moderate, intermittent traction resorted to. The result was that in ten minutes the head was delivered and rotated to the left, and the shoulder drawn from under the symphysis. Here there had been a medium sized head, waddling about the brim, with the face inclined toward the inlet. Correction to left occipital anterior was made by combining internal and external manipulation, and a safe delivery accomplished in fifty minutes from the perforation of the membranes: thus saving the mother from several years of anxiety, and the child from the dangers of a face delivery. Other illustrative cases also were cited in the course of the paper.

Healthy Sick Children.—This was the title of a paper by Dr. Lewis, delivered in New York, which was published in the Journal for June 21, 1913.

Changes in the Treatment of Syphilis.—This paper, by Dr. William S. Gottheil, of Manhattan, was published in the Journal for June 7, 1913. In connection with it a large number of lantern slides presenting various syphilitic lesions were shown.
globe, the cornea, the iris, the anterior chamber, the pupil, the crystalline lens, and cataract. The second part is devoted to the interpretation of the ophthalmoscopic signs to be observed in diseases and to the deductions from the author's own drawings. An exceedingly brief and unsatisfactory review of the chapter on the pupil, pages 96 to 133, may perhaps convey some idea of the nature of the work. First come the physiological mechanisms of the pupil. The diameters of the pupil, the count of the way in which meiosis is produced with the drugs and diseases that cause it, a similar consideration of mydriasis, congenital and acquired anisocoria, and the diseases in which the latter is a symptom, alternating transient anisocoria, the pupillary reflexes and the diagnostic significance of their modifications, congenital and acquired anomalies of form, with the causes of the latter; closing with persistent pupillary membrane. The entire book contains an immense amount of diagnostic information. It is well worth having and reading, but is especially valuable for reference.

The author's very wide experience in this special branch of abdominal surgery has made him well adapted to be the author of a monograph on the subject. The present edition brings the whole topic thoroughly up to date and, in preparing it, the author has found it necessary practically to rewrite certain sections of the book. He has had the practical nature of the subject uppermost in mind and has striven "to portray the disease in its clinical aspects for the benefit of students and practitioners whose experience is limited," and his purpose has been "to give the physician the methods of treatment are given in detail which the author has found after his many years of practical experience to give the best results. The most important subject that has necessitated revision is that of general peritonitis of appendicular origin. The recent advances in the operative treatment and the after-treatment of this complication have been such that the chapters in most textbooks have become hopelessly obsolete. In preparing the new edition the author has found that these cases must be very different from that of fifteen years ago, with its ninety per cent. mortality. The modern conditions such as Lane's band, Jackson's membrane, and movable evertum receive some attention by the author, but he devotes the greater portion of his discussion to the general peritonitis of the appendicular region, putting on a firm basis. In its new form the book is more valuable than ever in giving the last word on this most important branch of surgery.

The author has limited himself in this short work to a discussion of the conditions of the anus and rectum which are amenable to treatment in office practice. Local anesthesia is therefore relied upon chiefly in the operative treatment. The book is essentially practical and is a very useful addition to our literature, especially from a technical point of view. Many practical "points in the minor surgery of this region" are directed to the general surgeon, but also to the general practitioner, who is so frequently called upon to treat the less important ailments of the anus and rectum. The value of the x ray is demonstrated, not only in the diagnosis of abnormalities in the sigmoid flexure and rectum, but also in the location of fistulous tracts. The more common affections, such as hemorrhoids, fistula, fissure, pruritus, and polypus are discussed in full, and the most up to date methods of treatment which have stood the test of the author's wide experience are given in detail. The illustrations are profuse and very clear. The same can be said of the x ray plates. The prominent feature of the second, edition demonstrates the popularity of the book, as well as the rapid advances that have been recently made in these common but practically very important affections of this region.

Flora Médica Brasileirn. Pelo Dr. ALFREDO AUGUSTO DA MATTA, Da Facul-tade de Medicina da Bahia; de medicina de hospitais de Manaus; exencarregado do Labora-torio de Anayises do Amazonas, etc. Manaus: Seccao de Obras da Imprensa Official, 1913. Pp. 318.

This small work, written in Portuguese, describes the medicinal plants in certain parts of Brazil, and particularly in the state of Amazonas, and their uses. Common names being given with their synonyms, and the physical, chemical, and therapeutic properties of each being clearly, though briefly, described wherever possible, it represents a mine of information for seekers of new remedies, the majority of drugs described being strangers to our materia medica.

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers of the United States Public Health Service for the seven days ending July 2, 1913:

Cofer, L. E., Assistant Surgeon General. Directed to proceed to Ellis Island, N. Y., and make an inspection of the medical examination of arriving aliens, and in returning to make an inspection of the Delaware Breakwater quarantine station. Cumming, H. S., Surgeon. Directed to make a sanitary survey of the Poto- macc River, and the purpose water, to determine the source of pollution, while under the supervision of the director of the Hygienic Laboratory. Fox, Carroll, Surgeon. Directed, in cooperation with Dr. John S. Fulton, secretary of the Maryland State Board of Health, to examine the public health laws and regulations of Maryland, and make an investigation of the sanitary administration conducted under them. Frost, W. H., Passed Assistant Surgeon. Relieved from duty at the Hygienic Laboratory, and directed to assume charge of the investigations of the pollution of the Ohio River. Hasseltine, H. E., Assistant Surgeon. Directed to report at the Bureau of Medicine and Surgery, Washington, D. C., Wednesday, July 9th, for examination to determine his fitness for further duty in the United States Public Health Service. Kerr, J. W., Assistant Surgeon General. Detailed to inspect certain laboratories in England and Germany, with a view to granting licenses: also to attend, as a delegate on behalf of the United States, the International Conference on Infant Mortality, to be held in London, August 4 and 5, 1913, and the International Congress of Medicine, to be held in that city, from August 6 to 12, 1913. Kolb, L., Assistant Surgeon. Directed to report at the Bureau of Medicine and Surgery, Washington, D. C., on Wednesday, July 9th, for examination to determine his fitness for promotion to the grade of passed assistant surgeon. Leake, J. P., Assistant Surgeon. Directed to proceed to the Bureau of Medicine and Surgery, Washington, D. C., July 9, 1913, for examination to determine his fitness for promotion to the grade of passed assistant surgeon. Lumsden, L. L., Surgeon. Directed to resume investigations of typhoid fever in certain rural districts of Virginia, to be selected by the Virginia State Board of Health, to determine causes of its undue prevalence, methods of transmission, and measures necessary for its control. McCullin, John, Surgeon. Directed to proceed to certain counties in Kentucky, to be decided on after confer- ence with the State Board of Health, to take measures for the prevention and suppression of trachoma. Moore, Dunlop, Surgeon. Granted one month's leave of absence from July 10 to 31, 1913. Robinson, D. E., Surgeon. Granted one month's leave of absence from August 1, 1913. Wertenbaker, C. F., Surgeon. Directed
to take charge of the Cape Charles quarantine station during the absence of Acting Assistant Surgeon MacCaffrey, on leave.

Boards reconstituted.

Board of commissioned medical officers convened to meet at the Bureau on June 30, 1913, for the reexamination of a cadet of the Regular Sixty-two on the basis of his fitness for appointment to the grade of first lieutenant. Details for the board: Assistant Surgeon General W. J. Pettus, chairman; Passed Assistant Surgeon H. J. Warner, member; Assistant Surgeon R. A. Kearney, recorder.

Board of commissioned medical officers convened to meet at the Bureau, Washington, D. C., Wednesday, July 9, 1913, to examine Assistant Surgeons H. E. Hasseltine, J. P. Leake, and Lawrence Kolb to determine their fitness for promotion to the grade of passed assistant surgeon. Details for the board: Assistant Surgeon General L. E. Cofer, chairman; Assistant Surgeon General W. C. Rucker, member; Surgeon B. S. Warren, recorder.

Board of commissioned medical officers, which was convened to meet April 7, 1913, at the Bureau, Washington, D. C., for the examination of applicants for appointments as assistant surgeons, reconvened to meet on Monday, July 7, 1913, for the same purpose.

Boards of medical officers convened for the reexamination of applicants for appointment as assistant surgeons and for the presentation of questions for the written examination to meet at 10 o'clock a.m. Monday, July 7, 1913, as follows:

Marine Hospital, Boston (Chelsea), Mass., Senior Surgeon Fairfax Irwin, chairman; Surgeon H. W. Wickes, recorder.

Marine Hospital, St. Louis, Mo., Surgeon P. M. Carringtont, chairman; Acting Assistant Surgeon H. C. Wakefield, recorder.

Marine Hospital, Chicago, Ill., Surgeon J. O. Cobb, chairman; Passed Assistant Surgeon H. de Valin, recorder.

Marine Hospital, New Orleans, La., Passed Assistant Surgeon A. D. Foster, chairman; Acting Assistant Surgeon J. T. Scott, recorder.

Fort Stanton Sanatorium, Fort Stanton, N. M., Passed Assistant Surgeon F. C. Smith, chairman; Passed Assistant Surgeon F. H. McKeon, recorder.

United States Army Intelligence:

Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Army for the week ending July 5, 1913:

Bevans, J. L., Major. Reports his departure on leave of absence. Brooke, Roger, Major. Will return to his proper station, having completed his duties in Washington, D. C., Hill, E. C., Captain. Was retired from active duty in the Medical Corps of the United States Army on June 27, 1913. Huntington, Philip W., Captain. Ordered to West Point, N. Y., on August 28th, for temporary duty until October 10, 1913. Kean, Jef- ferson, First Lieutenant. Ordered to West Point, N. Y., on August 28th, for temporary duty until October 10, 1913. Pyles, William L., Captain. Ordered to West Point, N. Y., on August 28th, for temporary duty until October 10, 1913. Tarleton, L. O., First Lieutenant, Medical Reserve Corps. Ordered to temporary duty at Benicia Arsenal, Benicia, California, to take effect on the arrival at that station of First Lieutenant Julius C. Le Hardy, Medical Reserve Corps, and will then return to the commanding general of the Western Department and report for duty at Los Angeles, Calif. Ordered to West Point, N. Y., on August 28th, for temporary duty until October 10, 1913.

The following named officers of the Medical Corps have arrived at the Gettysburg Encampment: Major P. L. Boyer, Captain W. L. Little, Captain W. M. Smart, Captain C. E. Doer, Captain A. N. Tasker, Major C. C. Collins, and Captain H. S. Parnell.

United States Navy Intelligence:

Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Navy for the week ending July 5, 1913:

Births, Marriages, and Deaths.

Married.

Anderton—Newman.—In Catonsville, Md., on Wednesday, June 25th, Dr. George A. Anderton, of Greystone Park, N. J., and Miss Minnie P. Newman.

Blakes—Barney.—In St. Louis, Mo., on Monday, June 25th, Dr. John B. Blake, of Boston, and Miss Mary E. Barney.

Robbins—Bransome.—In Philadelphia, on Monday, June 30th, Bayard Bransome and Miss Ethel M. Bransome.

Locwine—Barry.—In Boston, on Monday, June 30th, Dr. Francis Lowney, of Fall River, Mass., and Miss Catherine Teresa Barry.

Myers—Whartenby.—In Wilmington, Del., on Tuesday, June 24th, Dr. Joseph Myers and Miss Minnie Whartenby.

Nichols—Eaton.—In North Haven, Conn., on Tuesday, June 24th, Dr. Ralph Wilbur Nichols and Miss Mary Margaret Eaton.

Died.

Bacon.—In New York, on Sunday, June 22nd, Dr. Stetson L. Bacon, of Port Norris, N. J., aged seventy-six years.

Boynton.—In New York, Washington, Mass., on Thursday, July 3rd, Dr. Frank H. Boynton, of New York, aged sixty-three years.

Cain.—In Pittsburgh, Pa., on Saturday, June 28th, Dr. William Jonathan Cain, aged twenty-seven years.

Carter.—In Tarrytown, N. Y., on Wednesday, July 2nd, Dr. H. Skeleton Carter, of New York, aged sixty-four years.

Essex.—In Hope, Ind., on Thursday, July 3rd, Dr. Herman L. Essex, aged thirty-eight years.

Fosta.—In Brooklyn, on Monday, July 7th, Dr. Frank H. Fosta.

Furness.—In Malone, N. Y., on Saturday, July 5th, Dr. Henry Furness.

Gegg.—In Philadelphia, Pa., on Wednesday, June 25th, Dr. Edward Rollin Gregg, aged forty-three years.

Hurlbut.—In Norwich, N. Y., on Thursday, June 26th, Dr. Phineas Hurlbut, aged forty-two years.

McFadden.—In Philadelphia, on Thursday, June 19th, Dr. William W. McFadden, of Norwich, N. Y., aged fifty-three years.

McFarlane.—In New York, on Wednesday, July 31st, Dr. Charles P. McFarlane, aged eighty-two years.

Morrill.—In North Andover, Mass., on Friday, June 27th, Dr. Charles P. Morrill, aged seventy-three years.

Robinson.—In Newark, N. J., on Sunday, June 29th, Dr. George W. Robinson, aged seventy years.

Webber.—In New York, on Wednesday, July 3rd, Dr. John G. Webber, aged seventy years.
A CASE OF DEMENTIA PRÆCOX WITH AUTOPSY.

By CHARLES W. BURR, M. D.,
Philadelphia,
Professor of Mental Diseases, University of Pennsylvania.

The case is interesting clinically because of the difficulty in diagnosis on account of the complexity and variability of the presentation; the patient seeming at one time to be suffering from gross organic brain disease, at another from pure hysteria, while the correct diagnosis, which was made only after long and careful study, was dementia præcox, and pathologically because the necropsy showed no gross lesion of any organ and the most thorough and minute examination of the cord and brain revealed no evidence of disease.

The patient, a white girl, nineteen years old, was first admitted to the Orthopedic Hospital and Infirmary for Nervous Diseases under the care of my friend, Dr. Francis Sinkler, and later transferred to my wards at the Philadelphia General Hospital (Blockley). Her parents stated that she had always been nervous and delicate, had never cared much for the society of boys or girls and, since puberty, had had many spells of depression. But little could be learned of her family history; not enough to justify any opinion as to whether it was medically good or not. Her illness began in January, 1913, when she received a slight wound of the right hand while at work; after which she immediately became very nervous. She had an hysterical attack, in the vulgar sense of the word, immediately after the accident, and continued to cry throughout the night. A few days later she began to be forgetful, speech became stammering, and she seemed to have lost the sense of pain; that is, when pricked with a pin she would deny that it hurt her; indeed she denied that she felt it, though she would withdraw the arm or leg which was pricked.

When admitted to the Orthopedic Hospital she was in semistupor and speechless. When spoken to she laughed in a silly fashion. She obeyed a few simple commands. For example, after being repeatedly told, she finally put out her tongue. It seemed as if the process of thought was greatly slowed, rather than that she was obtinate. Whether there was a blocking of the effert or afferent paths between the bulb and the cortex, or whether the trouble was cortical (mental), cannot, of course, be known, but her slowness certainly was not willful. It is hypothetically possible in these cases that a seeming mental sluggishness may really be due to a break between the cortical centres of thought and the tracks leading to or coming from them. The knee jerks were greatly exaggerated. Her weight was ninety-five pounds. The urine was normal. She paid no attention to the bladder or bowels. Both the Wassermann and Noguchi tests were positive. After a couple of weeks superficial bed sores appeared on the heels and sacrum. They developed not only on parts subjected to pressure but elsewhere. Her legs were drawn up on the abdomen and stiffened, and there was some little rigidity of the right arm. She held her hands up when asked. The second Wassermann and Noguchi tests, made two months after the first, and after salvarsan had been given intravenously, were negative. Dr. Thomas B. Holloway examined the eyes ophthalmoscopically (December 6, 1917) and found them entirely normal. Her mental state precluded the fields of vision. Early in December she began to have twitching of the right arm and right side of the face, most marked around the corner of the mouth. The right arm was at this time not spastic, but, when not twitching, was held flexed at the elbow. The knee jerks were normal.

There was neither a Babinski jerk nor ankle clonus. There were at times small continuous recurring contractions of the abductors of the right leg. On December 15th the Wassermann and Noguchi tests were both doubtful. By January 15, 1912, the bedsores were almost healed, her general appearance was better, all spasmodic movements had ceased, and she answered questions responsively, though she spoke but little spontaneously and never said to ask for water or to have something done for her. Altogether, she was greatly better both mentally and physically. On February 24th and Wassermann was made, and was also disappointing. The patient again ceased to speak, and would not obey any simple command save to open her mouth. She had no trouble in eating after food was put in her mouth, but she would not use her hands to feed herself. Her legs were held strongly flexed, but she used her hands occasionally. Often she would hold her hands uplifted for a long time and keep her gaze fixed on them. She had several other tricks of muscular movement and many spells of grimacing. She gave no evidence of paying any attention to anything going on around her.

On February 16th she was admitted to my wards at Blockley. When I visited her, she lay in bed taking no notice of her surroundings, seeming to be in a stupor, not speaking spontaneously or in response to questions. Both arms and legs were contracured and the contractions could not be passively overcome. Both thighs were flexed on the abdomen, the left knee was crossed over the right, and both legs were flexed at the knee. The knee jerks were increased. On February 20th she was still stupid and mumbled and talked incoherently. On March 5th she was much weaker. She would hold remnants of food in the mouth for hours, but did not choke in swallowling. When spoken to she made inarticulate sounds. Negativism was marked. Told to open the mouth or eyes, she closed them tight. Attempts to passively flex the head made the neck stiffen. There was some tremor of the head. The right arm was contractured in flexion, and also the fingers. There were numerous superficial bedsores on the shins, ankles, and buttocks, and several scars of old healed ones. She used the left hand to pull up the bed clothes, but did not voluntarily move either leg or the right arm; but if the right arm was passively lifted would move it about for a time and then lower it to the bed. She gave no evidence of feeling pain from pin pricks. The biceps jerk was simply present, the triceps very slight. The reflexes were so marked in the leg that it was impossible to tell whether the Babinski jerk, ankle clonus, knee jerk, and Achilles jerk were present or not. She was not in real coma, as was proved by the fact that she showed, by trying to pull up the bed clothes during an examination, that she disliked being exposed. At this time, at rest, the right eye wandered slightly up and out. The pupils were
equal and reacted to light. She paid no attention to the bladder and bowels. She died March 8, 1912.

At irregular intervals during the course of her illness she had several Sections of days at a time. The temperature chart was not characteristic of any disease. The temperature would remain between 100° and 101° F. for a week or two, then vary night and morning from 102° to 86° F. for another week or two, then be normal for an indefinite time. After another fever would recur. At first it seemed that the fever was correlated with the bedsores, but that turned out not to be true. There was always some fever when bedsores were present, but there was also fever at times when there was entirely healthy. Repeated examination of the urine proved the absence of cystitis, a frequent cause of fever. Fever is, of course, not a symptom of either hysteria or dementia praecox. What its cause was in this case I do not know. The contractures came and went. When I first saw the patient she looked like one of organic hemiplegia with the ordinary contractures of the palsied arm and leg, at other times all four extremities were contractured, or any one, and at still other times all the contractures would disappear suddenly. They finally, however, became persistent. Speech also varied; at first it seemed to be truly aphasic, later it was babbling, and finally the patient was mute. Her mental state, too, varied from apparent stupor to fair consciousnesse in true status.

Dr. Williams B. Cadwallader reports as follows concerning the condition of the brain and spinal cord: "The specimens were received some weeks after preservation in formalin. The brain is rather small and the frontal lobes are unusually flat. The convolutions and gyri are well defined, the membranes are not thickened, and there is no evidence of meningitis nor of lesions of the cortex. On cross section through the lateral ventricles a few brownish red minute areas are seen scattered diffusely throughout the basal ganglia and internal capsules, but there is no evidence of softening or of hemorrhages. In the pons, medulla, and the cervical and thoracic cord the same appearance is found, but in the lumbar cord it is absent. Microscopical examination (with the Nissl and alumhematoxylin and Weigert and Weigert's stains) Sections taken from the frontal and occipital lobes and the paracentral lobules show nothing abnormal. With the Nissl stain there is no chromatolysis. The cells are well formed and the nuclei are not displaced. Sections taken from the basal ganglia and internal capsules reveal no degeneration with the Weigert stain. The bloodvessels are not diseased, but are engorged with red blood cells, which are well stained. There are no perivascular infiltrations. Sections of the pons and medulla, cervical and thoracic cord, present the same appearance. The lumbar cord, however, does not show so much engorgement of the bloodvessels. The membranes of the spinal cord and brain are nowhere thickened, nor is there any evidence of rupture of cells. The cells in the anterior horn throughout the cord are normal."

When I first saw her in consultation at the Orthopedic Hospital the question was as to the possibility of brain tumor or serious cerebral vascular disease. She then showed hemiplegia with contractures, an apparent partial motor aphasia and hemiplegia. Brain tumor was excluded by the absence of the classical symptoms—vomiting, vertigo, choked disc—and by the history of the months of convalescence following the operation. Dr. Sinking and I felt sure that syphilitic vascular disease also could be excluded, and there was no reason to suppose that vascular disease from any other cause could be present. However, we were somewhat perplexed by the variability of the results of the Wassermann and Noguchi tests. We were forced, when the contractures and the speech defect suddenly passed off, to the conclusion that the disease was either hysteria or dementia praecox. I confess that for some time I was not satisfied with the results of these tests. By the time of her admission to Blockley the diagnosis was well established.

There is a similarity between dementia praecox and hysteria, and it is often hard to tell for some time in a given case with which disease we are dealing. The differential diagnosis is of great importance because of the difference in prognosis. An attack of hysteria is usually cured, though the hysterical temperament remains, and there are almost always recurrences which in time are recovered from, while in dementia praecox, though there may be a remission during which all symptoms disappear, or a cure of the first attack, if one dare speak of it as such, there is inevitably a recurrence and finally complete dementia. Hysteria may recur many times over a period of years, and no dementia result; dementia praecox always leads to permanent dementia after, in the most favorable cases, a few years.

The alleged cause of her illness, a trinitating injury, cannot have been anything more than a mere excitant. No healthy person would be made seriously ill by such an experience. There was no real shock—nothing to frighten, alarm, or horrify a normal girl. It is possible that the accident had nothing to do with her subsequent illness, but was a mere coincidence: it is more probable that she was in the prodromal stage of disease and ready to be influenced by any, even the slightest, stress. The real exciting cause, the material thing which acted on her organs, remains unknown. It is a very common thing for patients, and their families, to regard as the cause of nervous or mental illness any unusual, remembered thing which may have occurred soon before the illness became manifest. Sometimes, when the element of legal responsibility and consequent damages exist, there is a distinct motive for assigning an accident as the cause, but in this case there was no question of damages, since confessedly the accident was entirely due to the girl's own carelessness. The real predisposing cause was within the girl herself, in her nature and constitution. Her protoplasm had power to resist the stress and strain of life for only so many years, or, rather, it could only do a certain amount of work, and when that had been done she succumbed. Gowers has explained and several of his physiological processes, such as idiopathic muscular atrophy, on this theory (abiotrophy), and the same thing is a reasonable, though hypothetical, explanation of this case.

The total absence of any discovered cause of death is very interesting. None of the organs gave any signs of disease to the naked eye, and a careful microscopical examination of the brain and cord did not reveal any abnormality. Every now and again, in any large series of necropsies in a large general hospital, a case will be met with in which the lesions do not seem to be adequate to have caused death, but it is rare not to find any lesion of any kind. When such happens it is reasonable to assume either that some intoxication has caused death without producing lesions sufficiently marked to be discovered by our present methods, or that there has been a real protopathic exhaustion due to the inherent weakness of the protoplasm itself. The case was a true insanity, and not a mere febrile delirium, because the mental symptoms existed for weeks before any fever existed and were not influenced in any way later by the course of the temperature. Furthermore, contractures and articulatory disturbances are not a part of febrile delirium.
THE INTERNAL SECRETIONS AS THEY CONCERN THE GYNECOLOGIST.

By Samuel Wyllis Bandler, M.D.,
New York.

The internal secretions play, so important a part in the development of the body and mind, and so important a part in the development of vital structures and functions—they are such essential factors in preserving these functions and structures, and in supporting the upkeep of the body—that scarcely any field of medicine exists in which a study of the ductless glands is not to-day an essential point in the thorough understanding of normal and pathological processes.

The proper development of the body in the earlier years and up to adolescence is to a great extent under the control of the hypophysis cerebrials and thyroid. This development, associated as it is with the ripening of the genital organs and the sexual glands, determines to a great extent the question of stature and genitalism. Many of the glands of the body enter, each through its own particular field of work, and also influenced by its relations to other glands, into the realm of bony growth, ossification, form of the bones, metabolism, and the mental state. When a physician sees an adult patient, the size of the patient, the proportion between the body length and the length of the limbs, the shape of the pelvis, the amount of adipose tissue, certain peculiarities of the skull, hands, or feet, certain mental characteristics, many so-called minor details, such as distribution of hair, trichosis, etc., attract attention to the existence during infancy, childhood, or adolescence of certain alterations and anomalies of gland function, which show that at all times deviations from the normal in individual or related glands must be reckoned with. In other instances there is nothing in the physical makeup of the individual, nor in any of the points elicited by a careful history, to point toward any previous easily recognized alteration of function on the part of any gland or glands, and in such cases one must look for other than developmental alterations and tendencies, and must consider acquired irritations, injuries, and causes in the elucidation of the questions involved. Then comes a large class in which the exercise of the normal functions of the body for the purposes for which they were designed, or interference with such functions, or the failure to make use of such functions, or interference with these functions by disease or injury, are productive of those deviations in the nervous system, which practically constitute a pathological picture. We must not overlook a very large class who are in that stage, or in those stages eventually reached by all, where regression begins, where glands naturally begin to cease their former activity, where the interrelation between the glands is so readily upset, and where abnormalities in gland functions seem particularly to turn in the direction of nervous and mental diseases.

An important matter, and one which makes the study of the ductless glands so fascinating, is the interrelation between the glands. Animal experimentation has shown us how a removal of almost any gland produces changes, sometimes compensatory, in others. If the changes which were produced in one gland were always to produce the same changes in the others the question would be simple, but, as we may have increased function of the anterior lobe of the hypophysis, associated with function or excessive function of the posterior lobe, or vice versa, we may have an anomaly in gland function associated with increased or diminished function of one or other glands of the body. The pancreas, the pin cushion glands, the adrenals, the ovaries, the hypophysis, the thymus, the thymus, with their interrelations, give us an endless series of changes and modifications, physical, nervous, and mental, which are extremely difficult to classify. Each and every one of these glands is influenced by, or influences ovarian and uterine function and we, who are interested in gynecology, are called upon to give these questions our most earnest study. There is no doubt in my mind, after years of observation, that this matter has been splendidly put by Cushing, that in certain families Mendelian principles hold good. It is probable that some families have certain ductless gland peculiarities. There may be instability of the thyroid, there may be instability of the hypophysis, there may be early or late genital maturity. This instability may be evidenced by increased activity in some members or generations, or decreased activity in other members or other generations.

Almost the first questions which a gynecologist asks his patient are: How old were you when you first became unwell? Did your menstruation come every four weeks, or were there intervals of weeks and months? Were you well during this period and before each period? Were you able to play like other children, or were you kept out of school? A girl who begins to menstruate at thirteen, fourteen, or fifteen shows that ovarian and genital development were probably normal. A patient who answers that she was able to play at that time and was perfectly well probably suffered from no palpitation, no nervousness, no functional cardiac neurosis. We know the important relation which the hypophysis and thyroid bear to genital development. We know that increased or decreased function of the hypophysis in the preadolescent stage is productive of failure of full development of the genitalia and the genital glands. We know that decreased function of the thyroid is an important factor in producing failure in complete development of the genital glands. Here, however, care must be exercised to be sure that we are dealing with alterations in these gland structures, for we know that congenital smallness of the arterial system, associated with narrow arch of the aorta, for instance, may be associated with sexual infantilism. The diseases of childhood, if these exanthemata involve the ovaries and uterus, may retard or inhibit the development of the genital structures. Chlorosis, supposedly related to ovarian function, may, in these and later years, bear a relation to the points under discussion.

Infantilism may be due to failure in proper function of the thyroid, hypophysis, and other internal secretions, or it may be part of the general failure of development resulting offtimes in the type of partial, scattered, or general asthenia. Frequently this
Asthma is masked and is only brought to light by subsequent events and phenomena. The involvement of the sexual organs in these types of cases is not to be confounded with that form in which infragenitalism seems to be unconnected with any other ascertainable physical or glandular alterations, nor must it be supposed that in this type the secondary characteristics are always deficient or wanting. Just as we may find infragenitalism a factor to be reckoned with, we may find in supragenitalism some points of great interest. Supergenitalism and pubertic precocity may be primarily the outcome of precocious development of the genital glands or may be the secondary results brought about by primary affection of other glands. Hypophysal affections are frequently associated with gigantism, but generally with genital atrophy. Pineal tumors, however, produce abnormal growth in height, plus premature genital development. Suprarenal tumor results in exceptional development of the body, plus sexual precocity. Excluding these cases, there are a certain number which can be explained only by primary supragenitalism.

In physiological puberty, proliferation of the epiphyses soon ceases. Premature puberty is often associated with accelerated ossification, for the genital glands have a great effect upon the growth of the skeleton. Thus, the age at which genital maturity takes place has an important influence on skeletal growth, and early maturity is associated with short legs, for the ovaries elaborate a hormone which stimulates the process of ossification. The effect of late maturity of the ovaries is to increase the height, especially the length of the legs. All gland functions are naturally stimulated at puberty, and, in addition to the influence which ovarian maturity has on skeletal growth, the influence which the hypophysis has at this stage must be taken into consideration. Many of the rapid growths are due to hypophysal activity, and come within the realm of the normal; others do not. Since hypophysal hyperplasia may be responsible for the rapid body growth which normally occurs at puberty, an exaggeration of the growth may produce what is known as a "normal giant, an individual normally proportioned, sexually intact, with great physical strength."

The relationship between the ovaries and those other secretory organs which influence the growth of bone is sufficiently remarkable to attract attention, and castration is followed by changes in the thyroid, the thymus, and the hypophysis. In passing, it may be mentioned, that the principal role in osteomalacia is played by the ovaries. These glands have always been considered as a factor in chlorosis, in which the amenorrheic type is the most frequent. The diminished power of blood formation is supposed to bear some relation to the female sexual organs, since from them come stimuli which act upon the blood producing structures. In the younger years, before adolescence, anomalies of the hypophysis cause as a rule failure of development of the ovaries, the urethra, and the other structures characteristic of the female. After adolescence anomalies of the hypophysis result in atrophic changes in the genitalia. The same thing, lack of development of the genitalia, holds true with giants and dwarfs. In the one case there is too little secretion, in the other there is too much, and yet with either of these alterations genital dystrophy occurs.

The distinctions between the genitalia of the two sexes themselves constitute the "primary sex characteristics," but a number of differences which are not connected with propagation, but which are characteristic of the female sex are called "secondary sex characteristics." Among these are the greater tendency to fat under the skin, and the resulting rounding of the body, the width of the hips, and the marked development of the gluteal region, as well as the length of the hair, the absence of beard, and the difference in the larynx. The difference in the pelvis is very marked. There is a slighter development of the features of the face, especially the lower jaw. The brain is smaller. Physically, even as children, there is a taste for different forms of play.

The differences are already apparent between the ages of eleven and fourteen, as concerns the rounding of the features, the increase in the fat, especially in the manubrium, in the gluteal region, on the thighs, etc. The most important of the secondary sexual characteristics are the breasts.

The element of the ovary which is responsible, directly or through modification of hypophysis or other gland activity, for the constitutional physical changes which characterize puberty is not known, but some assert that it is possibly the interstitial gland structure. As a consequence of sufficiently early preadolescent castration, the acquired characteristics of sex may fail to appear. As a result of failure of ovarian function the secondary sex characteristics may be poorly developed, though the reproductive functions, covered by the follicles, may not be impaired. Castration never produces the positive characteristics of the opposite sex, but, when carried out early, results in a continuation of the infantile type. The ovary exerts its influence on the growth of bone, on the accumulation of fat, and on the character of the blood. Castration is followed by excessive longitudinal growth, a lack of proportion between the length of the trunk and that of the extremities. Removal of ovaries causes atrophy of the uterus, but has little effect on the vagina, almost none on the external genitalia, and very little on the libido. Therapeutically, castration produces splendid results in osteomalacia. At puberty, when the ovary begins to assert itself in the economy, the thyroid likewise begins to enter the field of observation and attracts attention through periodic states of overactivity. How much the ovary has to do with bringing on these secretory alterations in the thyroid is still unsettled, but, in my opinion, the ovary, which so dominates in many ways the functions of a woman's body and mind, is responsible, because of its relation to the thyroid, for many of those thyroid deviations of which I now speak, and which I may mention later.

Heart symptoms at puberty may develop for weeks or months before the first menstrual period. There is often an increased, objectively noticeable palpitation, which is frequently associated with vasomotor sensitiveness, blushing, tendency to pallor, tendency to fainting. There are cases where the pulse may be from 120 to 140. The symptoms usually occur in attacks, sometimes daily, sometimes at intervals of several days. When the period be-
gins the attack disappears, and usually recurs at the following periods in milder forms. Kisch describes the paroxysmal attacks of tachycardia with very rapid pulse, which occur some time before the first period, then each time before every following period, and may last several months after the establishment of the menstrual function. These patients show an increased irritability of the sympathetic. In them there is neither anemia nor chlorosis.

In certain patients the heart symptoms and vasomotor disturbances mentioned above occur before each period. Noticeable irritability of the heart at the time of menstruation is of course observed in most girls suffering from hyperthyroidism. The thyroid may then be swollen, or may show no change in size. Women with fibromyomata often have thyroid changes, especially if the fibromyomata are interstitial. The greater the proportion of connective tissue in the tumor, the more marked are the thyroid changes. Röntgen rays cause a diminution in size of the myomata and favorably affect the associated struma. This regression is said by Frankel to be due to the effect of the rays on the ovaries. Probably the tachycardia, so often associated with fibromyomata, especially with marked uterine bleedings and generally attributed to the bleedings, may be due to the thyroid changes. We all acknowledge the connection between myxedema and Basedow's disease, Addison's disease, etc., on the one hand, and varying degrees of amenorrhea on the other.

I wish, however, to devote a few moments to the question of relative and actual amenorrhea, especially when associated with obesity and occurring, as it often does, many years before the awaited climacterium approaches. It is of course recognized by all that the ovaries preside over menstruation and exert a trophic influence on the uterus; senile atrophy and lactation atrophy being simply physiological and expected processes, due to cessation of ovarian activity. We find a certain type of case in which menstruation grows gradually less, the menstrual molimina less pronounced, the uterus and ovarios smaller; associated with which is a progressive gain in weight. For years these cases have been a puzzle to me, and I have come to the conclusion that little can be done to reduce such patients in weight or to restore their menstrual function. I like to characterize these cases by the term "precocious menopause," and have previously explained them on the theory of an equal and harmonious diminution of function on the part of the thyroid and the ovaries. In recent months, especially since the work of Cushing has become known to us, we realize that a new explanation gives us a better understanding of the matter. A lowered function of the posterior lobe of the hypophysis, with a coincident disturbance in metabolism, is responsible for the gain in weight and for the ovarian atrophy, and in all probability is in many cases associated with thyroid lowered function. Here, again, we find ourselves in the position of explaining the cause for the changes in the hypophysis. With acromegaly, universally recognized as due to superfunction on the part of the anterior lobe of the hypophysis in the later postadolescent stages, the genital atrophy is usually so pronounced, and amenorrhea often so early a symp-

tom, that in the minds of many men the ovarian alterations have been considered the primary ones and the changes in the hypophysis as secondary. At any rate, the trophic relation between the hypophysis and the ovaries in the preadolescent and later periods seems to be closer even than the relations between the thyroid and the ovaries, and that is certainly saying much. The ovaries certainly bear some relation to certain excessive uterine bleedings. They are, after all, the cause of menstruation, and the vast majority of cases of relative or absolute amenorrhea are due to involvement of the ovaries, directly or through the influence of other glands or certain diseases. Why may we not expect symptoms of the opposite extreme with overfunction on the part of the ovaries, if they produce a congestion or hyperemia of so marked a nature that only slight disturbances in the uterus are necessary to result in menorrhagia or metrorrhagia? Some of these cases in adolescent patients seem to be due to a too rapid and sudden maturation of the ovary. There is often an inherited tendency, the mother having undergone similar troubles. This condition may be a family trait and may represent an inherited instability of the glands of internal secretion. Metrorrhagia may be due to a hyperemia resulting from underfunction of the ovaries and may be accentuated by masturbation. The normal uterus, lined with a normal endometrium, resists the premenstrual congestion up to that certain point when menstruation begins. The greatest wonder is that menstruation occurs with such marked periodicity and that the flow lasts a certain time and then ceases because the endometrium is bledd. the uterine wall contracts, and that substance secreted by the ovaries which is responsible for menstruation is thrown out of the system. If, then, we are dealing with an abnormal endometrium, perhaps hyperplastic through excessive ovarian stimulation, especially of the aderoid type, or if the uterus has lost its elasticity and if its contractile power is diminished, then even a normal ovarian congestion may, with perfectly understandable ease, produce menorrhagia or metrorrhagia. We observe these excessive bleedings very often in women in the late thirties and early forties, and they are usually healthy, well developed women. I have hysterectomized a large number of these, large enough to have my attention attracted to the fact that they have large, plump ovaries, and I have long since come to the conclusion that failure of the ovaries to regress at this period naturally prevents the uterus from undergoing atrophy, and the associated persistence of marked premenstrual congestion within the uterus of lessened elasticity readily explains the frequent bleedings to be found in the preclimacteric period.

I have always felt that the internal secretions had much to do with sterility, aside from the effect on uterus and ovaries. To my mind a normal functioning ovary evidences itself by a certain, supposedly normal amount of menstruation. With this as an accepted standard, and with the added weight of certain degrees of premenstrual molimina, we have the right to presuppose the existence of follicles which produce ripe ova. The facts that some women who conceive menstruate only every
two or three months, and that several cases have come under my observation of women who have borne children and have not menstruated for intervals of from one to two years (not because of lactation), do not nullify the general principles just enunciated, for they are only clinical points that guide us in forming an opinion. Hence, with relative amenorrhea, or with actual amenorrhea, or with the amenorrhea associated with obesity, we have a right to presuppose the possibility that the ovary may be at fault, either in not being what may be termed "ripe" or through being retained in atresic unbroken follicles, which is of itself an evidence of follicular weakness. In this type of case, and also in the form characterized by the various degrees of genital hypoplasia, other factors may come into play. The tubes may be very small, they may be tortuous, and, what is most important, the cilia may be involved. On the activity of the cilia of the tube depends the entrance of the ovum into the uterus. It is a natural supposition that the ovaries, through their trophic effect on the uterus, may be among the factors which control the action of the cilia. If we have absence of spermatozoa or inactive spermatozoa in the male, why may we not have inactive cilia in the Fallopian tubes? So that, with abnormalities in the ovarian secretion, or in diseases involving the thyroid or hypophysis, it is only a rational opinion and not a reckless conjecture to point toward the possibility or action on the part of the cilia as a possible cause of sterility, and to hold the ovary and thyroid or some of the other internal secretions responsible.

In gynecology, for years reflex annoyances have been supposedly produced in the nervous and digestive systems by abnormalities in the genital tract. No change in the position of the uterus has been too slight, no tear in the cervix too small, no palpable or pathological alteration in position or function on the part of the ovary has been too slight to be considered the cause, by reflex action, for slight and great changes in digestion, in cardiac activity, in the functions of the nervous system, in the realm of the mind, and in the field of pain. This reproach, I hope, is no longer borne by gynecology, that useless operations are advised because reflex causations are presupposed. As we view this question to-day we recognize that a very important class of patients, in whom there is a decided tendency to inelasticity and asthenia, come into the hands of the gynecologist, and especially those who practise obstetrics, who realize the truth of this statement. This asthenia may be constitutional and general, it may involve the nervous system or the circulatory system, it may be characterized by ptoses, or by lack of mental stability. Many of these cases go back to developmental physical alterations in infancy and early childhood and cannot be placed to the credit, so far as we now know, of any one particular gland, or set of glands.

At all periods of a woman's life alterations of the thyroid functions may occur. Lowered function may be so marked as to produce the classic symptoms of myxedema. Overfunction may be so decided that exophthalmic goitre is evident. But we are now on the threshold of unanimously acknowledging that underfunction may be of all degrees and overfunction likewise: so that the term hyperthyroidism is now of almost universal use. Anomalies of thyroid function concern the gynecologist, so far as menstruation is concerned, by occasionally producing amenorrhea; more frequently, varying degrees of diminished menstruation. The intimate relation between the ovary and thyroid is such that it is more than probable that changes occurring in the ovaries themselves influence the thyroid to underfunction or to overfunction. These anomalies in thyroid secretion, whether in the way of amount or quality, concern the gynecologist because of the alterations which they produce in the digestive system, in the nervous system, and in the psyche.

It is worth while asking why thyroid affections in the form of myxedema and Basedow's disease are so much more frequent in women than in men. Whatever the real explanation may prove to be, it also serves a purpose by giving an explanation for the marked instability of the thyroid in the wide field of hypothyroidism and hyperthyroidism of minor grades, sometimes affecting the genital sphere, the digestive functions, the nervous system, or the psyche. I may take a moment to state that it is the theory of intimate relation between ovary and thyroid to be true, if either of these glands stimulates the other, and at the same time has an antagonistic action, then the elements of menstruation, pregnancy, and the climacterium, plus the numerous injuries to which the ovaries are subjected, furnish a very rational basis for the frequent alterations in thyroid function and give us at least such this which may be stated, namely, that whatever may be the cause or causes for thyroid alterations in the male, those same causes naturally act with much greater readiness in the female. Then, too, comes the question of the uterus. I have often said that no woman is really so well as that one whose uterus plays no further part in her economy. So long as menstruation takes place, so long as the uterus and its lining undergo their premenstrual changes as a result of ovarian stimulation, just so long have we a factor which in turn reacts upon the ovaries and also upon the thyroid. So that the interrelations between the ovary and the thyroid, on the one hand, between the ovary and the uterus on the other, and then, too, between the uterus and thyroid, furnish another reason for the instability of thyroid activity.

Therefore, the almost universal recognition of the frequency with which hypothyroidism and particularly hyperthyroidism influence certain periods, stages, or even the whole, period of a woman's life open to us a clearer understanding of the causation of these phenomena, which for so many years have been erroneously attributed to pelvic reflexes, and recent observations show that in this field, too, the hypophysis takes a position which demands attention.

Knowing, then, the relations which the important glands bear to the ovaries and genital functions, and the relation which the ovaries bear to other glands, we in gynecology must remember to view with suspicion in every case the diagnosis that cessation of menstruation, as such, is a cause of nervous or mental disease, or vice versa, and must be on the alert to correlate, whenever justified by accurate diagnosis, nervous and mental symptoms on the one hand and disturbances of menstruation or genital abnormalities on the other, by referring both to...
affections of the ductless glands, and thus separate ourselves, so far as is correct, from the former fixed ideas concerning hysteria, neurasthenia, and reflex neuroses. The nerve phenomena in the climacterium show variations from the phlegmatic type to the excitable type. The psychic variations run from melancholic and psychasthenic to manic forms. In many cases the annoyances are clearly the result of changes incident to the climacterium. In others they resemble various forms of mental diseases and seem oftentimes to have nothing to do with the inter-glandular upset. Each is of course necessary to separate the forms which are coincident with the preclimacteric or climacteric phase from the forms which are due to the alterations of that period. Some women go through this time of life with scarcely a ripple to mar their good health, while others are miserable and unhappy for months or years. There are women who are in this so-called change of life state (if that be used to signify an abnormal relation between the secretions) during the greater part of their life or for certain months of their existence, or preceding a few or many, or all, of their menstrual periods. They suffer from the same variations in the way of annoyances as the patients of the class mentioned who are about to go or are going into the climacterium. There is too much ovarian stimulation, or too little ovarian secretion, there is too much thyroid actually or relatively, or there is too little thyroid, or there is a play between these various alterations.

We are concerned in the climacterium with a progressive failure on the part of the ovaries to produce their normal secretion. Coincidently, and because of this failure, there occur alterations in other glands in the body, the thyroid being the one most particularly involved. During a woman's existence her good health depends, to a very great degree, on a proper balance, so to speak, between the ovaries and the thyroid. Overactivity or under-activity of one affects the activity of the other, and this balance is frequently upset at certain menstruation, or after certain causes have been productive of certain changes, during lactation, in the post partum period, sometimes during pregnancy, etc. If the ovary and thyroid diminish as to the secretion which they produce in equal ratio, the patient goes through her menopause calmly and without upset. If the ovaries diminish with too great rapidity and the thyroid too slowly, the patient is in a state of hyperthyroidism. The thyroid function diminishes too quickly, the patient may be in a state of hypothyroidism.

134 West Eighty-seventh Street.

THE FACULTY OF PARIS IN THE SEVENTEENTH CENTURY.*

By Frank Baker, M.D.,
Washington, D. C.
Professor of Anatomy, Georgetown University.

The seventeenth century was a period of transition, the ideas and forces of the middle ages having not altogether passed away and those of modern times being as yet undeveloped and crude. The feudal system, although broken by the decline in the power of the nobles, still ruled the world in spirit, and the freedom of the individual was as yet an unrealized dream. The Church, which by its solidarity and force had kept Europe from lapsing into barbarism, had by its unquestioned rule become a tyranny and largely controlled intellectual life. Everywhere there was an exaggerated respect for authority which often stifled progress. In medicine the writings of the great ancients, Aristotle, Hippocrates, and Galen, were still regarded as supreme authority, and exhaustive of the subjects which they treated.

The Faculty of Paris was the name given to the entire body of physicians authorized to practise medicine in that city; what we should now call a medical association. The rules and regulations by which they were governed were, however, much more strict and precise than anything now in vogue. The organization claimed to go back to Charlemagne, and it is known that it was an independent corporation in 1280. It was formerly called the Physicorum Facultas, or Faculty of Physics; hence our own word physician. It fulfilled the function of an academy of medicine and of a board of health, and was the final authority in medicolegal matters. The organization had a strong ecclesiastical flavor. Medicine, during the middle ages, was usually practised by monks and subject to the discipline of the Church. We shall therefore find in the customs and ritual of the Faculty much that reminds us of conventual usage.

The number of physicians in this body was not very large. During the seventeenth century it varied from 100 to 110, about four being added each year from the graduates. There was thus one regular physician to about 5,000 inhabitants. The ratio to-day is one to 960. It was a close corporation difficult of access, whose members commanded respect, having a dignity only second to the noblesse and often counting members of that body among its numbers. The cost of a medical education was so great that it was beyond the reach of any below the state of the wealthy bourgeoisie. A candidate had to have a preliminary degree of master of arts or of philosophy, as he must be able to discourse fluently in Latin, which was still used to distinguish the learned from the vulgar herd. He must be a Roman Catholic, not even the request of the king being allowed to prevail against this.

The teaching was wholly theoretical, the students listening to lectures which began at seven o'clock in the morning and continued till noon, commencing again at one. The lecturer often added to the reading explanations and remarks. Questions on the lectures were asked once a week. There were but few professors and they were frequently changed, every member of the Faculty being supposed to be competent to teach any subject. Dignity was upheld by appropriate dress, as the statutes provided that each professor should pledge himself to teach in a long gown with wide sleeves, a doctoral cap on his head, and a knot of scarlet ribbon on his shoulder. After two years of attendance the student was subjected to an examination, which lasted a week, and if he passed he became a bachelor of medicine. He took a solemn oath: To
observe faithfully the practices and customs of the Faculty and never in any case to act against it; to treat with honor and respect the dean and all the masters; to assist the Faculty against any opponents, especially illicit practitioners.

All this was only preliminary. He had to be examined in botany during the next summer, and the following year had to dispute against members of the Faculty—not his teachers—on some selected subject, sometimes such as appear to our modern minds trivial and absurd, such as: Is it well to get drunk once a month? Are women imperfect works of nature? Are bastard children brighter than those which are legitimate? Should the phases of the moon be considered when we have the hair cut? These disputations were of almost incredible length, lasting from six a. m. until noon. Commenced by nine doctors, who attacked successively, they were continued toward noon by all present. During Lent still more vigorous examinations were held, the bachelor attending from five a. m. to twelve, and disputing with all present. Each one of the doctors in attendance having the right to propose two questions. For seven hours he had to pit his wits against the assembled Faculty, men trained and exercised in subtle dialectics. The candidate was also required to furnish food and wine for his adversaries.

After two years' trial of this kind the candidate could become a licentiate and be granted the right to practise. You will observe that he had had no clinical experience; indeed, many never saw a patient during the whole course of their study. The course was wholly in words, words, words. As Montaigne acutely says, they knew their Galen but not their patients. The license to practise was administered in the most solemn manner by the chancellor, a canon of the Church, in the presence of representatives of the Court and the municipality. The candidate having knelt before him, the chancellor announced in sonorous Latin: "By authority of the apostolic see which I wield in this region I confer upon you the right to read, interpret, and administer the medical art here and throughout the world. In the name of the Father, the Son, and the Holy Ghost." The chancellor then proposed some questions to the candidate highest on the list. These also were sometimes quite puerile, such as: Does drunkenness have any curative effect on a quartan fever? Whence came the water that flowed from the side of Christ after death when he was pierced by a spear? This ceremony, over, the entire assembly proceeded to the cathedral, where the chancellor made a short prayer in which he admonished the new licentiates that they now belonged in a special manner to the Church, for which they must sacrifice all things, even their lives. Needless to say, the whole ceremony was in Latin.

The licentiate was not yet a doctor, not entitled to full privileges as a member of the Faculty. After six weeks or more, and on application being made, the dean having inquired minutely into the life and manners of the applicant, the Faculty voted on his admission. If this was favorable, a session was held at which the applicant was solemnly admonished on the importance and dignity of the medical profession, and still more questions were proposed. Some days after, he was expected to visit each one of the governing body and invite him to attend the ceremony of his reception. When the day for this arrived the applicant was required to swear to observe the rights, statutes, laws, and customs of the Faculty, to contend with all his might against anyone who practised medicine illicitly. "Vis ista jurare?" Do you swear this? solemnly asked the grand apprictor. "Juro" replied the licentiate—a phrase to become afterward famous as we shall see. Receiving then the doctoral cap and the accolade borrowed from the ceremony of knighthood, he became a full fledged doctor.

The result of all this exaggerated respect for learning, for books, and for authority was necessarily the formation of an ultraparadic and conservative body, jealous of innovations, a foe to progress, and wedded to tradition. Their peculiarities of dress and bearing were the target for many popular lampoons. This is one of the most famous:

Assume a most pedantic brown, Some Greek or Latin quout; Have on a wig and grotesque gown Of satin furred about; For such things almost make, we own, A doctor out and out.

The results of the narrow and bigoted attitude of the Faculty were very striking. Scientific medicine in France fell to a low ebb. While remarkable discoveries were being made in Holland, Germany, England, and Italy, France remained unproductive. Except some slight matters in anatomy by Riolan, nothing was brought forth. Harvey's demonstration of the circulation, Aselli's discovery of the lacteals, and Pecquet's discovery of the thoracic duct were forbidden to be taught.

Another reactionary restriction which did great harm to the Faculty was its attitude with regard to surgery. Strange as this may seem to our modern minds, instruction in this important branch was not included in the curriculum, and the most bitter opposition was made to any who ventured to consider surgeons as of equal rank with the regular physicians. There were several reasons for this antagonism. It probably arose in the first instance from the monkish traditions that affected the Faculty, the Church always forbidding the shedding of blood; also from the fact that surgery was considered a handicraft and therefore unworthy the attention of those engrossed in the interpretation of Hippocrates, Galen, and Avicenna. The surgeons did not tamely submit to be thrust out of the learned professions. It was Pigay, one of them, who used the oft quoted simile concerning a comparison of the ancients and moderns: "We may say that we are a child standing on the shoulders of a giant, we can see all the giant sees and something more." They established for themselves a separate school, the college of St. Cosmo, and claimed the privilege of teaching anatomy. The prime difficulty was the obtaining of material, which was only granted to the Faculty. On the

1A more complete account of this ceremony, and of the entire organization of the Faculty, is found in Maurice Raynaud. Les médecins au temps de Molérate. Paris, 1886.
2Translation of Chaterfield-Taylor.
rare occasions when the bodies of criminals could be procured for dissection the surgeons would sometimes surround the scaffold and carry off the warm cadaver in spite of the authorities. As it was absolutely necessary for the members of the Faculty to have some surgical assistance, they relegated this department to a class of uneducated men, the barber surgeons, who practised blood letting as a trade, and the profession which Ambroise Paré had adorned was nearly destroyed. Persecuted incessantly and pursued by royal decrees, they finally sank into temporary insignificance, to revive again in the next century.

Trained and inured to di斯putation as were the members of the Faculty, it is not surprising that they had violent disagreements among themselves, usually upon some point of diagnosis and treatment. There was always great jealousy of outside influence, whether this came from the rival Faculty of Montpellier, from the surgeons, or from some bold innovator like Paracelsus or Van Helmont. Yet there were not wanting in the Faculty itself those who were open to novel ideas, and the controversies were often bitter, as we see from the letters of Guy Patin, the dean and censor of the Faculty, a man of the keenest wit and a most uncompromising adherent to the ancient doctrines as interpreted by the commentators.

Bleeding, cautiously recommended by Hippocrates, was carried to a most shocking extreme. Bouvard, physician in chief to Louis XIII, bled that monarch forty-seven times in one year, Guy Patin bled a child seven years old thirteen times in one month, he also bled an infant of eleven months and another of three days who was attacked with erysipelas. He had the courage to perform the operation on himself seven times for a cold. He expresses himself very bitterly about a poor physician who did not believe in bleeding and declared he would rather die than be bled, which he promptly did. "May the devil bleed him in the other world; the scamp, the atheist!" He defends this strange treatment by saying that all Parisians live too well, and consequently have a plethora which needs to be reduced. There was also the dreaded caco-chymia, or corruption of the humors, which had to be relieved. Botal compared the blood in the human body to the water in a good spring, the more that we draw off the more it is replenished.

Another famous controversy that raged at this time related to antimony. The somewhat apocryphal story about this substance is that it was discovered early in the sixteenth century by Basil Valentini, a monk of Erfurt, who tested its virtues by feeding it to pigs, which then became very fat. He then tried it on his fellow monks, who immediately became sick. He therefore named it antimony—delerious to monks. Its virtues were highly vaunted by Paracelsus, and its prompt and vigorous emetic action recommended it to those who wished to reduce the "peccant humors." As it was recommended by the Faculty of Montpellier, the Faculty of Paris declared it a poison and forbade its use. There was, at that time, but little known of the proper doses of powerful medicines, and, besides, the antimony then obtained was not free from arsenic, which explains the fattening of Basil Val-
You can readily see the force of well directed shafts of ridicule, emphasized by all the accessories of the theatre, and repeated in this manner. Probably no author has ever equaled Molière in the delicacy of his satire. It resembles the celebrated sharp sword of Baron Münchhausen, which cut off a head so neatly that the victim never knew it until he came to blow his nose, by which act the head was thrown actively into the room. To be sure, he sometimes descends to farce, even a little broader than a cultivated taste approves, but he had been a "barn stormer" and knew his audience. He first appeared before the King in 1660, in the inimitable comedy of Les Précieuses ridicules, an untranslatable title which may be roughly rendered The Utterly Utters, in which he satirized the foolish whimsies of a certain set that had become the vogue at court. The courtiers were immediately up in arms and tried to shut up his theatre and prevent him from playing, but the King had been vastly amused and took Molière under his protection.

A few words should be said about the "grand monarque," the "sun king" who shaped the destinies of France for nearly seventy years. He was not really a very great man nor a very wise one. He had a great capacity for work and was a fair judge of men, using them as tools to advance his own interests. It was probably some indescribable psychic quality of presence and his care never to be caught at a disadvantage that gave him his enormous prestige. He was icily callous, regardless of the feelings of others, greedily selfish, and fond of adulation. It was through his powerful influence that Molière was able to maintain himself and to freely satirize the follies of the time.

I cannot dwell upon the famous plays in which he held up to the world Tartuffe, the hypocrite; Harpagon, the miser; M. Jourdain, the sham gentleman; Alceste, the misanthrope; my concern is with those in which he attacked medicine and the medical profession. In these he undoubtedly had the sympathy of the King, who had suffered many things from many doctors. In Don Juan, a comedy first produced in 1665, and which-served afterward as the foundation for Mozart's opera, Don Giovanni, we find Don Juan's attendant Sganarelle (the Leporello of Don Giovanni) disguised as a doctor. He says:

Do you know, this dress has obtained for me some consideration: People salute me when they meet me and come to consult me. Five or six country fellows and their women came to ask my advice on different diseases. It would be a droll thing if they should be cured and come and thank me for it.

Don Juan. Why not? Should you not have the same privileges as other doctors? They have no more to do with curing patients than you have: Their art is mere pretense. You will find that everything which may proceed from a lucky chance and the powers of Nature will be attributed to your remedies.

Sganarelle. Why not? Don't you believe in medicine?

Don Juan. It is one of the greatest errors of mankind.

Sganarelle. You do not believe in senna, cassia, or emetic wine?

Don Juan. Why should I?

Sganarelle. You have a very unbelieving disposition. Yet you know that emetic wine has lately made a great noise in the world. Its miracles have converted the most incredulous minds, but three weeks ago I saw it produce a marvelous effect. There was a man who had been at point of death for six days; they did not know what to do for him as none of their remedies were any good, at last they took it into their heads to give him an emetic. Don Juan. He recovered then?

Sganarelle. No, he died.

Don Juan. What a wonderful effect!

Sganarelle. Surely. For six days he had been trying to die and this killed him at once. Could anything be more efficacious?

In Love as a Doctor Molière makes a more direct attack. Lucinde, in order to avoid a marriage into which her father is forcing her, feigns illness and her alarmed parent calls in four doctors. The bright and saucy servant remonstrates with the father:

"What do you want of four doctors, Sir, is not one enough to kill anybody?"

"Hold your tongue, four heads are better than one."

"Can't your daughter die without the help of these gentlemen?"

"Do people die by employing doctors?"

"Indeed they do; I knew a man who contended that you never ought to say that such and such a person died of fever, or an inflammation of the lungs, but she died of four doctors and two druggists. Not long since my cat fell off the top of the house into the street; for three days he could not eat nor move; luckily there are no cat doctors to physic and bleed him, or it would have been all over with him."

"Hush! the doctors are coming."

"Now, you will be highly edified, they are going to tell you in Latin that your daughter is sick."

The doctors then proceed to consult, but instead of discussing the patient, converse about trivial matters. A difference of opinion has arisen between two practitioners and the rules of the Faculty had been violated, the junior consultant daring to differ from his senior. The senior killed the patient, but the worthy quartette hold him to have been entirely right and the junior wrong, although his advice was better. "A dead man is only a dead man and of but little consequence, but the whole profession suffers injury if a formality is neglected."

It should be remembered that at the time this play was produced a very scandalous scene had recently occurred at the death bed of Cardinal Mazarin, where four doctors had disagreed totally as to the manner of treatment, and had denounced each other in no measured terms. The doctors in this play were carefully made up to imitate the personal appearance of those physicians, and the dialogue that ensues when they come to prescribe for the patient is evidently based on the rumor of that famous consultation. The first doctor finds "great heat of the blood" and proposes to bleed, the second finds "purification of the humors" and proposes an emetic. High words ensue. "An emetic will kill her. "If you bleed her she will die. "Do you remember the man you killed a few days ago?" "And you the woman you recently finished off?" etc., etc. They leave, and the remaining couple prescribe purgatives and acrodines. "Your daughter may die, but you will at least have the consolation of knowing that she died in due form. It is better to die according to rules than to recover contrary to rules."

The puzzled father rushes out to get some quack medicine, and the denouement is made by Lucinde's maid bringing in the lover disguised as a physician, who with much palaver makes a totally different diagnosis and prescribes a mock marriage with himself, to which the father agrees and finds too late that the marriage is valid. During the play the
two angry physicians meet a third, who expresses sentiments which we may feel were shared by Molière himself: "Are you not ashamed to show so little prudence and quarrel like young fools? Is it not enough that we should dispute with our learned contemporaries and ancient masters without revealing to the laity our quarrels? The science of medicine is not improved by this. Since heaven has allowed people to be infatuated with us for so many centuries, let us not disabuse them, but profit by their follies. Let us agree before our patients, so that the happy issue of the illness may be attributed to us, and our blunders be laid at Nature's door. Let us not destroy the happy fondness for an error which gives bread to so many people."

In The Doctor in Spite of Himself the farce is even broader. A drunken scamp of a woodcutter who has picked up a smattering of medical terms is forced by a good beating to pose as a doctor, and finding it "the best of all trades" diagnosticates in gibberish, which the company think is Latin, a case of pretended drunkenness, and assists his patient to elope with her lover. It is exucrattingly funny.

The pretended doctor in his discussion of the malady reverses the relative position of the heart and the liver, and the father says, "I have no doubt your reasoning is most excellent, but there is one thing which puzzles me, the position of the heart and the liver. It seems to me that the heart is on the left side and the liver on the right." "Formerly it was so," replied the doctor, "but we have changed all that." This is an excellent instance of the way in which Molière used the events of the day to heighten his effects. The medical profession of Paris was much excited just then over a case of *situs inversus viscerum* which had recently been discovered, and much discussed. The wit of implying that the doctors had power to change the position of the viscera at will, and had probably done so, must have pleased the audience.

The attack upon the doctors was kept up in *M. de Pourceaugnac*, a comedy with ballet interludes that were composed by Lulli. There is in this also a consultation between two doctors, one of whom is described as follows:

He is a man who knows his profession as I know my rosary and who, were his patient to die for it, would not depart one iota from the rules prescribed by the ancients. For all the gold in the world he would not cure a patient with other remedies than those prescribed by the Faculty; he is expeditious and despatches his patients promptly. If you must die, he is the man to help you to do it quickly.

This learned man prescribed for the patient, who is not in the least sick, as follows:

Firstly, in order to cure this obdurate pleothera, and this luxuriant cacoecymy throughout the body, I am of the opinion that he should be liberally phlogistomated, that is to say that he should be liberally and copiously bled; in the first place by the basilic and then by the cephalic vein; and even, if the disease be obstinate, the vein in the fore-head should be opened, and the opening made large, in order that the thick blood may come out; and, at the same time, he should be purged, deobstructed, and evacuated by suitable and proper purgatives, that is to say by cholagogues, melanagogues, etc.; and as the variable source of all the evil is either a thick and feculent humor or a black and gross vapor which obscures, infects, and contaminates the animal spirits, it is necessary that this treatment should be followed by a bath of pure and clean water, with plenty of whey, in order that the water may purify the feculence of the gross humor and that the whey may clarify the blackness of this vapor.

There is much more of this; indeed, it is hard to select; but I must not weary you. It sounds strangely to us, but the remarkable thing about it is that it is not a caricature. It can be easily matched by serious prescriptions taken from Fernel and other distinguished members of the Faculty. It is indeed remarkable that Molière was able to imitate so perfectly the Galenical jargon of the day. The scene ends rather broadly, the patient rushing off protecting his *derrière* by an arm chair and pursued by a number of apothecaries each armed with an enormous syringe.

We now reach Molière's last play, *The Hypochondriac*, in which he continues his biting satire upon the Faculty. It calls up tragi-cal memories, as upon its fourth representation, our author, playing the title rôle, was stricken on the stage and died of a hemorrhage a few hours later. It was, perhaps, from personal experience that he places the following words in the mouth of the brother of the hypochondriac:

Between ourselves, I consider medicine as one of the greatest follies of mankind. It is looking at it from a philosophical point of view. I cannot think of anything more ridiculous than for one man to undertake the cure of another. The springs of these machines of ours are a mystery which, up to the present, men do not understand; Nature holds too thick a veil over our eyes for us to know anything about it. Most of the doctors know a great deal about the classics, they can talk in fine Latin, they know the Greek names for every disease, but as for curing them, they know nothing at all about that. Their art excels in pompous gibberish, in specious twaddle which substitutes words for sense, and promises for performances.

My limits will not permit me to dwell upon this wonderful play which is truly a masterpiece of medical satire. It should be read as a whole, as it fairly bristles with good things. It ends with a ballet and spectacle in which the ceremony of graduation of a doctor is parodied. In many respects this closely approaches the actual ritual. It is thought that Molière had here the assistance of some of his friends who were members of the Faculty. The ceremony is given in macaronic Latin; the candidate being propounded certain questions, for example, "Why does opium produce sleep?" replies

Quia est in eo
Virtus dormitiva
Cujus est natura
Sensus assoupire.

whereupon the chorus of the Faculty exclaim:

Bene, bene, bene, bene respondere
Dignus, dignus est entrare
In nostro docto corpore.

In this there is a dig at the inmates faculties of Aristotle, which placed in every object special and peculiar virtues which gave it its qualities. Malebranche asked whether a carriage followed horses because of a *pratice* virtue. Being asked how he would treat a dropy, the candidate replies:

Clysterium donare
Postea seignare
Ensuita purgare.

The same answer is given for the treatment of asthma, and for hectic fever with headache and pain in the side, each time with the felicitations of the chorus. A fifth doctor asks:
Mais si maladía
Opiniatrix
Non vult se garire
Quid illi facere?

and receives the same answer. The candidate then swears to observe the statutes of the Faculty, to follow in all consultations the old methods, to never use any remedies but those approved by the Faculty, no matter if the patient should die on his hands. At each clause the candidate solemnly pronounces “Juro.” It was while pronouncing this word that Molière succumbed, and his enemies did not fail to allege that it was a judgment of God for his impiety toward the Faculty.

His death was truly tragic. Feeling woefully weak and ill, he had been implored to close the theatre and not to play, but he made it a point of honor not to give up, saying: “What can I do? There are fifty poor workpeople who live on their daily wage; what would they do were there no performance?” The actor’s profession being under the ban of the Church, burial in consecrated ground was refused. “What!” said Madame Molière to the canon who turned back the coffin, “you refuse burial to a man to whom you ought to consecrate altars!” It is true, for he was the greatest reformative force of the period, Boileau said of him, “Thy lightest jest is worth a learned sermon.” Burial was finally secured by orders of the king. Though easily the most eminent man of letters of his time, the prejudice against him was such that he was never elected to the French Academy. One hundred years after his death the Academy placed in its assembly room a fine bust of him, with the following inscription:

Rien ne manquait à sa gloire,
Il manquait a la nôtre.

Nothing was wanting to his fame,
T’was ours that needed him.

I have given considerable space to the work of this illustrious man because he was really the chief force that caused a reformation of medical education in the seventeenth century. “Cervantes laughed Spain’s chivalry away,” and I think we may truly say that from the laughter of Molière grew the forces that led the medical profession in France to abandon its antiquated methods and enter upon the career of investigation and research which has ever since distinguished it. The decree against antimony was rescinded before Molière’s death. They held out longer against the circulation of the blood.

The circulators (meaning charlatans in Latin) were decried by the entire Faculty, even by Riolan, whom, it will be remembered was the only opponent whom Harvey deigned to answer categorically. It was with reference to this controversy that Boileau and Bernier drew up the celebrated “Burlesque Decree” in the form of a judicial order, as follows:

In view of the fact:
That an unknown person named Reason, by an illegal and lawless procedure, has attributed to the heart the charge of receiving the chyle formerly belonging to the liver;
And also has made the blood circumgyrate throughout the entire body with full powers to wander, stray, and circulate with impunity through the veins and arteries:
Having no right nor title to do these things excepting only the authority of experiment, whose testimony has never been allowed by the Faculty—
The Court orders:
That the chyle go straight to the liver without passing any more by the heart,
That the liver receive it;
Forbids the blood to divagate further, to wander and circulate throughout the body, under penalty of being entirely given over and abandoned to the Faculty.

Forbids Reason and her adherents to attempt to cure by bad remedies such as pure wine, powdered cinchona bark, and other drugs not approved nor known by the ancients.

And in case of irregular cures by the said drugs it is permitted to the members of the said Faculty to proceed, in their usual manner, to throw the patient into a fever, and to reproduce the illness from which he formerly suffered, in order that he may be treated according to the rules, when if he does not recover he will at least pass to the other world sufficiently purged and evacuated.

And in order that the orders of the Court may be obeyed, it has banished forever the said Reason from the schools of the said Faculty; it forbids her to enter them, and to trouble and disturb Aristotle in the possession and enjoyment of the same under pain of being declared a Jansenist and a favorer of innovations.

In 1673, the year of Molière’s death, Louis XIV established at the Jardin des Plantes a special chair for the dissemination of the new discoveries of the circulation of the blood and of the lymph.

The paralyzing effect of the Faculty could not wholly stop progress in France; those who traveled and saw what was being done in other countries came back with minds somewhat enlightened. It is to the honor of Riolan that he persuaded Louis XIV to establish the Jardin des Plantes, where Duverney made important investigations and infused such spirit into his work that even noblemen flocked to hear him and witness his demonstrations. Montpellier, though suffering from an inebrius like that of Paris, was still able to produce Vieuussens, whose researches on the anatomy of the brain deserve mention.

The progress was, however, mediocre when compared with that seen elsewhere. In England, besides Harvey, Glisson placed our knowledge of the liver on a secure foundation; Wharton and Needham investigated the salivary glands; Willard described more fully the brain and the cerebral sinuses; Highmore the cavities of the face and the seminal ducts; Sydenham greatly improved the diagnosis and treatment of disease. In Italy, Malpighi made a host of discoveries, anticipated the cellular theory, and gave a correct idea of the nature of glands; Borelli worked out the mechanics of the bodily structure; Bellini obtained a fair idea of the structure of the kidney, and Wirsung discovered the pancreatic duct. At Leyden, Leeuwenhoek, with his rude microscopes, discovered infusoria, spermatozoa, and many other minute matters; Van Horne and Nick demonstrated the lymphatics and the thoracic duct, Sylvius increased our knowledge of the brain and established clinical teaching as a necessary method. Swammerdam, at Leyden, and Ruysch, at Amsterdam, perfected the art of injections; Bartholin, at Copenhagen, studied the lymphatics, while Stensen worked upon the brain and glands, anticipating our modern idea of tracts for the conduction of impulses in the central nervous system. At Wittenberg Schneider correctly described the mucous membrane of the nose, completely overthrowing the prevalent doctrine of the brain as a secretory organ.
COUGHLIN: SENSE OF SMELL IN DIAGNOSIS.

By Robert E. Coughlin, M. D.,
Brooklyn, N. Y.

Old medical works rarely referred to odors, but as time goes on one notices in the newer publications occasional references to odors, at times in a way to make it appear that they may be used as real characteristic signs of diseased conditions. There can be no denying the fact that we should use every means at our disposal in endeavoring to make a diagnosis. Helen Keller says that many of us who have all our senses do not use them—a rebuke by one who cannot see, hear, or talk, except as she has lately learned to use her voice after years of teaching. How many have the sense of smell and never use it for any useful purpose? As the writer understands it, our duty is to use this sense if it helps us in our study of diagnosis, but to the minimum extent.

Probably every physician and surgeon, as well as experienced nurse, uses the sense of smell either instinctively or as the result of experience in diagnosticking disease or appreciating diseased conditions. That this is an important sense often forcing itself upon us hardly any one will deny. It is difficult to imagine its extreme usefulness if it be carefully developed and cultivated along given lines. There is food for thought in such a subject. Are we using this sense as we should in the recognition of disease? Our sense of sight we have developed or tried to develop in every possible way. Inspection as the result of observation has its proper place in medicine, and no article or book is ever written, and properly so, on the diagnosis of disease without space being devoted to inspection as an aid in diagnosis. The sense of hearing has its place, especially in auscultation, nervous diseases, and ear work. The sense of touch—feeling or tactile sense—has its proper place in abdominal and chest percussion, as well as in gynecology and obstetrics. The sense of taste has a very small place in diagnosis, unless it be along the line of materia medica and toxicology. In uranalysis we hear of the sweet taste of saccharine urine. The sense of smell undoubtedly has its place in diagnosis, although no attempt has ap-

1788 COLUMBIA ROAD.

THE SENSE OF SMELL AS AN AID IN DIAGNOSIS.*

Two individuals as a rule will agree as regards unpleasant odors and agreeable odors. A fragrant flower will be in a degree as fragrant to one person as to another and will always call forth an expression of pleasure on the face of the individual smelling it, while a foul odor will cause a contortion of the facial muscles, signifying a feeling of disgust. The sense of smell occurs at an earlier period in female than in the male infants, and girls and women have, as a rule, a better sense of smell than boys and men. It is well known that the lower animals have the sense of smell acutely developed, owing to the relative size of their olfactory bulbs and the greater distribution of their olfactory nerves. The scent of the hounds in the chase is well known. Lower types of men seem to have scent similar to animals, but not at all to the same degree. Paradoxically, the higher up you get in civilization the more acutely developed is the sense of smell. The esthetic sense is accompanied by a delicate sense of smell, while in the lower walks of life this sense seems to be blunted. An illustration of this is afforded by the stifling and malodorous atmosphere in which many illiterate people pass their lives. Different races of people have an odor peculiar to themselves, as, for example, negroes, Chinese, and Indians. Different nationalities also have a distinctive odor, as, for example, the Italians, Irish and Russians.

Men have an odor about their persons which differs from the odor belonging to women as a class. The young person differs in odor from the adult of the same sex. The old man has an odor peculiar to himself, likewise the old woman. Brunetts have a distinctive odor; likewise the blond; and in the former the odor is in certain types very positive. Red haired persons have a peculiar odor about their bodies, especially those with dark skins.

The odor of the infant is said to be of butyric acid; that of old people of dried leaves. Occupational odors of different kinds may also be considered, as workers in different occupations will have about their persons odors of the kind which they work in. People will also carry about their persons the odor of their living rooms. Habits of cleanliness or lack of cleanliness have a good deal to do with the odor about a person. The odor of the body before a bath may be very strong, whereas immediately after the bath a freshness may take the place of a strong disagreeable odor. We are not, by the way, running much of a chance of a limitation of our study by too great cleanliness, for it is the opinion of the writer that most humans do not bathe sufficiently.

It is generally conceded that different individuals under ordinary circumstances possess odors which are distinctive and peculiar to them. These particular odors are changed when the body is diseased. A healthy person's odor differs from the same person's odor in a time of disease. As observed by the writer, different diseases have different odors, and these odors are about the same in different individuals. Thus, the odor of phthisis is about the

*Read before the Norwegian Hospital Alumni Association, April 9, 1913.
same in all individuals, especially during the later stages of the disease. Different diseased conditions differ in odor as regards the location of the diseased focus in the body. For instance, pus gives off a different characteristic odor when the situation of the disease is in the chest, in the ischiorectal region, or in the appendix. Different body organs when diseased give off characteristic odors. Special odors emanate from the skin, hair and scalp, breath, arm pit, feet, perineum, prepuce, mons veneris, vulva and vagina, and from the menstrual fluid. Each secretion and excretion has its own particular odor. Normal feces have a strong odor, while in certain diseased conditions (as jaundice, for instance) there is almost complete absence of odor about them. There is no unpleasant odor in normal fresh urine; ammoniacal decomposition of bacteria is the cause of the so-called urinary odor. There is a disagreeable odor in decomposing albuminous urine. According to Emerson, a diagnosis may be made from this alone. There is said to be an intolerable odor in cancer of the bladder and deep inflammatory diseases of the urinary tract. Chabrie believes in a characteristic odor in certain conditions of abnormal metabolism with incomplete combustion, such as diabetes and oxaluria. There is said to be a special odor in chyluria, and even in slight hematuria. Emerson has noticed a strong odor of sulphuretted hydrogen in certain nephritics, even when the urine is quite fresh. Valerian, coffee, asafetida, and various foods are excreted as such in the urine. Copaiba, cubeb, etc., cause odorous bodies. Turpentine produces an odor of violets in the urine. After eating asparagus there is a characteristic odor attributed to methyl mercaptan. The odor of semen resembles a mixture of flour and water, crushed leaves, or sawed bone, according to different observers. There is thought to be an odor about the bodies of the dying. Pet animals will leave their masters when they perceive this odor. A “mousey” smell has been noticed about the persons of dirty adults as well as children. Smoking interferes with the sense of smell. A few persons find it impossible to smoke when they have a coryza without experiencing an attack of nausea. A well-known chemist has developed his sense of smell very successfully to distinguish compounds in his laboratory. Parlor games have shown that the sense of smell tires very easily. One may not perceive the odor of kerosene after a few attempts at forcing the sense to recognize different substances. The sense of smell is excited by substances in a fine state of subdivision or in the gaseous state floating in the atmosphere. Sniffing or short inspiratory movements bring these substances in contact with the rod cells which make up the special olfactory mucus membrane. A moist condition of the mucous membrane favors the act of smelling. Most of the olfactory nerves are distributed to the upper and middle part of the nasal cavity. No motile cilia are in this area. The extreme delicacy of smell is shown by the fact demonstrated by Valent in that perception of two millionths of a milligramme of musk is sufficient to excite the olfactory nerves in men. The acuteness of the sense of smell is greatly improved by practice. A boy named James Mitchell, who was deaf, dumb, and blind, used his sense of smell like a dog to distinguish persons and things. Electrical stimuli give rise to olfactory sensations. Flavor depends on the sense of smell.

Rufus Ephesus (97 A. D.) described the passage of the olfactory nerve through the ethmoid bone. Carbonieri (Revista Clinica, 1888) contributed a clinical observation which gives some information as to the position of the olfactory centre. The patient suffered from a number of epileptic convulsions, during which he always complained of a nauseating odor not perceptible to others. Post mortem examination revealed a tumor in the occipitotemporal and hippocampal convolution, or at that portion of the brain in which the olfactory centre has been placed by Ferrier, Munk, and others. Dr. William H. Bayles reports the case of a gentleman who persistently perceived a smell which resembled a bug. He sincerely believed that a bug had crawled up his nose and become lodged there. Upon examination an abscess of the frontal sinus was found.

Continent young men are said to smell more strongly than the unchaste. The emanations from the body during sexual excitement are well known. In men this is more marked than in women, except in rare instances. Just prior to intercourse the odor in both sexes differs from that which is perceived following the act. A close observer may by proximity to a man or a woman after the orgasm perceive a peculiar and characteristic odor. In women this odor, like that prior to intercourse, is not quite as perceptible as in men. Grimaldi states that the odor from a man's breath, skin, or both during sexual excitement is of rancid butter or chloriform. Girls and young women during menstruation give off an odor from the breath quite distinct from that of the menstrual fluid. In insanity of a sexual character hallucinations of smell are encountered by alienists. Scents of white flowers, like syringa or gardenias, sexually excite some persons, as does the personal odor of a beloved individual or certain artificial perfumes. Lack of sexual vigor is frequently accompanied by a neuroasthenic sensitiveness to sexual odors. It is generally conceded that as the sole factor in sexual selection olfaction must be rare, sight always taking precedence. The very same odor may at one moment be highly agreeable and, at the next, highly unpleasant, according to the emotional attitude resulting from its associations.

In the Symptomatology of Disease. The odor of the breath has some importance, especially in tuberculosis. It may be fouler than the sputum in the cup. Some maintain that they have diagnostic small cavities by this sign before they could have been discovered by physical examination. The sputum when fresh has almost no odor; when it is allowed to stand a very positive odor is given off. In tuberculosis and bronchiectasis the odor of the sputum is heavy, sweet, and penetrating; in pneumonitis empyema, like that of old cheese; in purulent bronchitis, fetid. In pulmonary gangrene it has the worst odor of all. (Emerson's Clinical Diagnosis.)

Dr. Algrenon T. Bristow, in a paper entitled A Case of Streptothycosis (Long Island Medical Journal, November, 1912), says: "We are all familiar with the characteristic odor of pus produced by the colon bacillus." Dr. Harvey Cushing,
in describing his book, Pituitary Body Disorders, page 226, a case presenting a "syndrome of precocious sexual adolescence," says: "There is excessive secretion from the cutaneous glands with a most offensive odor." The Lancet, February 1, 1913, draws attention to the fact that many cases of ill health which have been attributed to lead poisoning are not really due to this form of poisoning, but are mainly if not wholly owing to a foul mouth condition. Dr. Robert Abbe, in the Medical Record of March 15, 1913, in a paper on Malignant Disease of the Tongue and Mouth, says: "When the tongue cancer reaches the stage of the foul excavated furrow along the half tongue, with a heaped up mass of new growth about it, looking like an over cooked sausage which has burst its skin, we have reached a point in the patient's endurance which is intolerable." Dr. Virginius Dabney, in a paper in the New York Medical Journal of March 15, 1913, on The Connection of the Sexual Apparatus with the Ear, Nose and Throat, says: "The marked increase in odor from the nose in ozenous cases at the time of the monthly flow, noticed by Mackenzie and Trousseau, has been my observation to this extent, that those who have atrophic rhinitis without ozena, had it at this period of ovarian activity." Dr. M. Gross, in a paper in the Medical Record of November 30, 1912, on Disinfection of the Intestine by Insufflation of Oxygen, says: "In putrefaction there is a mixed type. The feces are dark, of putrid odor, etc." In a case of chronic fermentative and putrefactive catarrh which he reports the odor of the feces was offensive, and in a case of colitis he describes the stool as soft, dark, alkaline, and of offensive odor. In necrosis of bone we are apt to perceive a rather characteristic odor. Patients with incontinence of urine have about their person a pungent urinous odor. Dr. Richard C. Cabot, in his recent book on Differential Diagnosis, makes mention of the sense of smell in many places.

The Sense of Smell as a Real Diagnostic Aid in Different Diseases and Diseased Conditions. Foulness of the breath is met with in four groups of conditions: 1. Septic and putrefactive changes within the nose and mouth; 2. septic and putrefactive changes within the lungs; 3. ingestion of certain substances such as tobacco smoke, garlic, onions, spirits, whose products are excreted by the lungs and saliva; 4. severe toxic conditions.

The nature of the trouble in the mouth may be tartar, septic gums, carious teeth with particles between them, pyorrhoea alveolaris, hypertrophic or atrophic rhinitis, ozena, septic tonsillitis, squamous celled carcinoma of mouth or tongue. Dentists tell us we must remember that bridge work will harbor all kinds of germs, as well as maggots alive and dead and in various stages of decomposition. Rarely will one find a foul breath in a perfectly healthy person with no signs of disease; not even flatulence or any bowel congestion. In ozena the secretions have an extremely offensive odor. The patient as a rule does not perceive this odor, owing to impairment of the sense of smell. In purulent inflammation of the middle ear the discharge has frequently an offensive smell. In chronic purulent diseases of the middle ear the purulent secretion simply dries, and later becomes changed into caseous masses which have an offensive smell. In abscess of the brain the contents of the walls of the abscess are of the nature of greenish, decomposing pus, which usually emits a most offensive odor. There is frequently an offensive odor from the breath. In septic thrombosis of the sigmoid sinuses the pulmonary symptoms are accompanied by expectoration, streaked with blood or having "a prune juice" character, giving forth in some cases a fetid or even gangrenous odor.

In typhoid fever there is generally a foul condition of the breath. The odor about a typhoid fever patient is quite marked, owing to the emanations from the body and the discharges, especially if there be diarrhea. This characteristic odor is rather sharp and stinging to the sense of smell, "a semicadaverous musty" odor as Nathan Smith says. In smallpox there is said to be a sickish odor, especially during the stage of suppuration, like the odor of sweet potatoes, according to some. In scarlet fever the breath often has a heavy, sweet odor. In diphtheria there is a very characteristic odor about the patient, depending upon the severity of the infection and the extent of the membrane. The old fashioned gangrenous sore throat was undoubtedly diphtheritic in character. The odor is fetid when the membrane reaches the back of the nose, as a rule. Almost any experienced person can make a diagnosis of diphtheria by this odor of the breath alone. In septicemia and pyemia the odor of the breath is foul. In pulmonary tuberculosis there is a characteristic odor about the patient, aside from the odor of the breath before alluded to. This odor is pungent and emanates from the skin and sweat glands of the patient. It may be perceived on the underclothing after removal from the body. In rheumatic fever we have an acid sour smelling odor from the sweat glands, and this particular odor is not noticed in any other disease.

In diabetes mellitus we have the sweet odor of the breath sometimes called "the acetone breath." This is a fairly constant symptom, and once recognized will always be appreciated. In ulcerative stomatitis we have a fetid or putrid sour mouth condition, with a very bad odor to the breath, and this is also the case in mercurial stomatitis or pytalisism. In supplicative tonsillitis the odor to the breath is foul, and the odor of the discharge is very characteristic. Dyspepsia in itself may produce a bad odor to the breath, as will any of the toxic conditions affecting the alimentary canal.

In cancer of the stomach the vomited matter consists of food and mucus in grayish or dark, sour smelling fluid. (Osler.) Children with gastrointestinal conditions have a sour smelling odor about their mouth and bodies. In some appendicitis cases we have the characteristic odor of the discharge, denoting ulcerative gangrenous appendicitis. In severe toxic conditions affecting the peritoneum the odor of the breath is foul, and this condition also obtains in intestinal obstruction. Bronchiectasis is also accompanied by a foul breath; likewise abscess of the lung and empyema. Gangrene of the lung, as has been mentioned, has the distinction of producing the worst odor of all.
In uremia and puerperal eclampsia there is a urinous odor about the body. This emanates from the skin and sweat glands, and is very pronounced and diagnostic. In fecal fistula there is always a disagreeable odor in the discharges. Abscesses in different parts of the body may produce odors which are very pronounced, especially old multiple ischiorectal abscesses. Ulcerating cancer in general will cause the production of odors, but there is one kind of cancer which is especially known for its foul smelling discharge, viz., nonoperable cancer of the uterus. Incomplete abortion will cause a bad smelling vaginal discharge, as will the leaving of secundines or portions of the placenta after full term labor. If the child be dead in the uterus the odor of the discharge, which comes from the vagina and may contain exfoliated epithelium, is as a rule fetid. In death of the fetus the breath is fetid. (King, p. 144.) In endometritis there may be a very bad discharge per vaginam. The odor from the uterus following normal labor where everything has gone on successfully should be free from any suspicion of bad odor, and the same is true after abortion under the same circumstances. During labor there is an odor about all women. This is changed when the membranes rupture, and becomes negative or nearly so after the birth of the child under normal conditions. The breath is very foul in postpuerperal sepsis.

Alcoholism may be diagnosed by the odor of the breath. In bone involvement of the middle ear there is a very characteristic odor. In cholesteatomatous masses in the middle ear the odor is that of Camambert cheese. One observer has noticed an odor in the breath of patients suffering with an ulcer of the cornea. In the active stages of measles there is present a very characteristic odor which is difficult to describe. There is said to be a cadaverous odor in children with tuberculous enteritis. In pregnancy there is a distinctive odor about women; one observer going so far as to express the opinion that it is possible to make a diagnosis from this sign alone.

ILLUSTRATIVE CASE REPORTS.

Case I. W. C., came to the writer for relief from pains situated in the upper extremities, along the course of the sensory nerves. No patella reflex. Other reflexes normal. Breath smelled strongly of alcohol. He denied the use of this at first, but later confessed he was a free user of it. Diagnosis, alcoholism.

Case II. H. M., aged thirty years. Complained of an extremely bad odor emanating from his person when he became sexually excited. He described the odor as fishy, and stated he had intercourse with his wife. Wished to know if anything could be done about it as it was very disagreeable. When his wife was spoken to about the matter she said she had never noticed any such odor about her husband's person under any circumstances. This appeared peculiarly strange.

Case III. The writer was summoned late in the evening to the bedside of a woman who was supposed to be dying. The husband was under great excitement, was walking about the room attired in a short garment, the evening being particularly warm. As he approached the writer an odor was perceived about his person which resembled freshly sawed bone or spermatic fluid. Careful inquiry revealed the fact that the couple had just had intercourse, withdrawal was performed, and the culmination of the act had not been accomplished as far as the wife was concerned; the same leaving her in a hysterical condition. The odor of semen led to the correct diagnosis in this particular instance.

Case IV. A young man presented himself with all the signs and symptoms of neurasthenia. In examining him at his request, he feared phthisis, I perceived the odor of tobacco on his person which was constantly emanating from his skin. Inquiry revealed the fact that he was in the habit of smoking at least fifty cigarettes daily.

Case V. The writer was summoned in the middle of the night to the bedside of a woman who was supposed to be dying. Her husband said he had been awakened from a sound sleep by her calling out to run for the doctor as something horrible had happened. Although the night nurse could be located she was engaged in the course of making her rounds. The patient had been heard to exclaim to her husband: “It’s my time again!” When the writer entered the patient's room his olfactory sense at once told him that defecation had just occurred. Upon very careful examination nothing more than a very loose bowel movement in the bed was found. After close questioning our supposed patient confessed that she had had a most horrible dream or nightmare and was so scared that she lost control of her sphincters. This frightened her still more as she “thought they were coming out as she expressed it, and consequently she cried out for help. In trying to extenuate the circumstances the husband said: “It never happened before,” and the weary writer answered: “Well, let it never happen again.”

Case VI. R. K., aged twenty-one years. Habits good; negative family history. Chief complaint, extremely bad odor about feet. Bathing did not help condition. Along with the bad odor there was extreme sweating. Diagnosis, hyperidrosis. Malodorous feet are quite common. Profuse sweating is often due to this condition. The odor of the feet under these circumstances is very offensive to the patient, as well as his friends. One is reminded of the little girl who when her mother had complained: “Say, mother, I’m going to eat that kind of cheese that smells like punkey feet; but isn’t?”

Case VII. Woman past middle life, who complained of bad odor and extreme itching of vulva. Said she had diabetes. Was very obese, weighing about 260 pounds. Bathing and astringents helped the condition to some extent but not entirely. An examination of the urine showed a large amount of sugar. In rare instances we find the same odor and pruritus present in patients without evidence of disease.

Case VIII. A patient of Dr. M. Pregnant; labor about due. Slight jaundice present; anxious expression of countenance; fetid odor breath; vaginal discharge fetid; no fetal heart sounds heard. Diagnosis, fetal tetanus with sepsis. Diagnosis confirmed by autopsy.

Case IX. In R. D., a woman of 48, delivered by cesarean section of a full term child fifteen days prior to the time when the writer was called in. Dr. W. insisted that everything had come away, placenta, membranes, etc. Lochia profuse odor and foul smelling; temperature normal. Diagnosis, sepsis, suppurative. Donches cleared the condition in a few days.

Case X. Patient of Dr. S. One week after a normal labor about due. Slight jaundice present; anxious expression of countenance; fetid odor breath; vaginal discharge fetid; no fetal heart sounds heard. Diagnosis, probable infection of the bladder by the colon bacillus. Hexamethyleneamine and sodium benzoate cleared up the condition very promptly.

Case XI. In C. X., was heard of an ectopic section at the third month; profuse and fetid vaginal discharge; temperature normal; all signs of infection absent. Curettage cured the condition.

Case XII. Mrs. S. Three days after full term labor the vaginal discharge became fetid and profuse. Temperature 105° F.; pulse 120; expression anxious. Diagnosis (which was later confirmed), retained piece of membrane.

Case XIII. Dr. M.’s case. Very bad odor to vaginal discharge on the fourth day following a normal labor. Retained piece of placenta was removed by finger.

Case XIV. The writer was called to see a sick child Christmas Eve, 191:3. The chief complaint by mother, very bad smell to child’s breath. Wrote made a diagnosis of diphtheria before looking at throat because of characteristic odor. This child had no sore throat, and in consequence the mother never thought to look for membrane. Diagnosis was confirmed by clinical course of disease and bacteriological examination of culture.
ODORS AS RELATED TO HYGIENE.

All are familiar with the agreeable odor of fresh, pure air, likewise the disagreeable effect on the sensibilities of bad air, so called. One has only to think of the disagreeable odor of the subway, the ill ventilated moving picture house, the badly ventilated bedroom as we find it after a night's occupancy, and by comparison the fresh, pure air in the country on a clear day or on a stormy day when the rain drops strike a new pine shingle. Aids in the diagnosis of unhealthy odors may be used along the line of discovering the origin of the bad odor, as, for instance, leaking gas fixtures in homes and places of business, poorly ventilated living rooms, smoky rooms, disagreeable odors from kitchens, toilets. wash basins, sewer pipe leaks, etc.

Trillat in the Archives des sciences physiques et naturelles, June 5, 1912, reports experiments concerning the growth of pathogenic bacteria when exposed to air containing putrid gas. He found that diphtheria bacillus and plague bacillus grow very rapidly under such circumstances. The experiments were conducted in the laboratory and out of doors. He believes that putrid gases from the soil cause changes in milk and meat after a thunderstorm. The general impression is that breathing and living in bad odors, such as those from leaks in sewer pipes, from out houses, or from decaying animal and vegetable matter, are a source of disease. In coal mines the miners are said to wear canary birds in cages on their hats for the purpose of watching the effect of the bad atmosphere on the constitutions of the birds. When the atmosphere becomes bad the bird will faint, and this is a sign to the miner to beware. Before the bird faints he will wilt; this also is a sign of impending danger.

Dr. S. P. Goodhart, in an article on atypical children (New York Medical Journal, XCVII, page 750) says:

For instance, a horror of death can often be traced to the impressions in childhood of the funeral ceremony, the house of mourning, the memory of all the highly emotional features of that period of stress and suffering. This has frequently helped to aggravate a nervousness in sensitive children. I have been able to bring the emotional complex out of the subconscious by stimulating the olfactory centre; that is, by allowing the patient, while in the hypnoidal state, to smell a tuberose, a flower so common at funerals.

The atmosphere in a neighborhood may be tested by the olfactory sense. The smell of chemicals, smoke, slaughter houses, tanneries, etc., all contribute to make a neighborhood more or less undesirable. There have been many attempts to eliminate smoke in certain cities, as, for example, in Chicago, where the smoke is measured and data carefully recorded. Tobacco smoke in living apartments undoubtedly does harm, especially where there are growing children. What may be a disagreeable odor to one person may be quite agreeable to another person. Odors experienced in childhood are as a rule remembered in all the after life. The odor of new leather gives a very agreeable sensation to most people. The odor of coffee grounds is especially offensive to certain individuals. Particular odors will cause certain persons to faint. as, for example, the odor of iodiform, colloidion, ether, or tuberose. A perfume maker may have two hundred different odors in his laboratory, yet he can distinguish them all. Probably nothing is really indorous. In conclusion, the writer wishes to make the statement that bad odors and good odors have their place in the study of medicine, in the development of the olfactory and esthetic sense, and that the sense of smell is a useful adjuvant in the diagnosis of disease and abnormal conditions.

CREATING FALSE MOTOR PATHS.*

By Max Strunsky, M. D.,
New York.

This article is a plea for a more thorough understanding of the principles on which muscle education is based, so that a more scientific technic for the treatment of chronic infantile paralysis can be constructed. In recent years so much has been written on the surgical and mechanical treatments of this disease, and so little that is actually good on muscle education, that the latter is forced to occupy a subordinate position in the therapy, as compared with the newer and more advertised methods. Even more conducive to the disrepute of muscle education than the overbalanced literature is the way it is practised both by private physicians and in institutions. The physician always wants to do the big things for infantile paralysis. Preventing the inevitable deformities by constructing good braces or correcting the deformities by tenotomies, etc., naturally attracts his immediate attention. He plans and often performs operations for tendon transference, arthrodesis, and even nerve grafting. On the other hand, muscle education is so time consuming and so simple as to seem undignified for him to practice himself. He invariably, therefore, leaves the gymnastic part of the treatment without adequate supervision to the nurse, masseur, or the patient's relatives, with the result that innumerable cases are met with in which patients have not only not received the benefit they might have had from scientific exercise, but have been actually harmed by faulty gymnastics. The object of this paper is to point out a few of the glaring mistakes which are frequently made in gymnastic treatment.

The movements of the body are executed by two sets of muscles; the direct and the auxiliary. In paralysis, the direct muscles being involved, the patient learns to accomplish the movements by employing those auxiliary muscles which were spared. Also, being unable to move directly, he is forced to perform vicarious movements. He avoids the use of paretic muscles, for it is hard work to use them, especially, as is often the case, when so little strength remains. To avoid this hard work the patient unconsciously does the easier thing, that is, he uses the auxiliary muscles. So strong is this tendency to avoid the use of the paretic and substitute the use of the auxiliary muscles that, in treatment, it is not only necessary to insist that the patient make continued efforts to overcome this tendency, but also to watch the movements constantly, for if left alone he will immediately revert to the habit he has acquired. Moreover, he learns to manoeuvre his auxiliary muscles in so subtle a

*Read before the members of the Staff of the Hospital for Deformities and Joint Diseases, April 8, 1913.
way as to give the impression that he is using the paretic muscles. This he does so naturally as to deceive even an experienced instructor. It often happens that the patient suddenly swings his limb in a way which seemingly must necessitate the use of the paretic muscles. On scrutiny, however, it is discovered that it is only a new movement which he has learned, and that he has helped himself with the auxiliary muscles after all. It is apparent, then, that when children who instinctively resist contracting their weakened muscles, and use their auxiliary muscles instead, are taught gymnastics by persons who do not know anatomy, the paretic muscles escape the exercise, and the brunt of it falls upon the auxiliary muscles, which become overworked. Needless to say that the opposite is the aim of muscle education.

It is obvious that in order to administer muscle education, it is not only necessary to know anatomy, but also to be able to reason anatomically. Otherwise one cannot know in what position to place the limb so as to frustrate the action of the auxiliary muscles, or be able to tell during the movement which muscles are carrying the burden and which are in repose, or even to know the difference between auxiliary and direct muscles. However, even with gymnastic treatment, most patients make favorable progress. Their limbs fill out, their trophic disturbances lessen, and their gait grows stronger. This blinds the physician and prevents him from discovering the wrong principle in the treatment. I have made a study of a number of infantile paralytics who have improved under various treatments, with the object of determining what constituted the improvement. I was surprised to find that in the majority of cases the favorable progress was not due especially to any perceptible increase in the strength of the paretic groups, but mainly to the development of the auxiliary muscles. It is easy to understand that the filling out of a withered limb can also be caused by the increase in bulk of the auxiliary muscles; that the modification in the vasomotor disturbances may be brought about by the increased circulation in the limb from any form of exercise, and that the slight improvement in gait may be due to the greater agility with which the patient has learned to execute the vicarious movements. But of course, this does not mean that the pathological lesion of the child has improved. On the contrary, in several of such so-called improved cases, there was even a decrease in the bulk and strength of the paretic groups, as shown by actual measurements and responses to the electric current. So that in these cases, though the patients were seemingly improved, pathologically they had really regressed. The fact, therefore, should be remembered that unless muscle education, in place of gymnastics, is used in the treatment of these cases, the paretic muscles will manage to escape the exercise more or less, and some entirely so. The harm of this can easily be imagined, especially when the muscles in question are already in the grip of atrophy and degeneration caused by paralysis of the vasomotor nerves. The harm of inactivity is not limited alone to the muscles, for physiologically they are not separate entities, but links in the structures which produce and express motor impulses, namely the nerves, the motor cells in the cord, the motor cells in the brain, the motor tracts, etc. Increased degeneration resulting from disuse is not limited, therefore, to the muscles alone, but affects all the above structures. This, however, is the least of the evils which result from the arrested function of the paretic muscle. A far greater evil, in my opinion, lurks in the vicarious movements. In performing the vicarious movements the patient develops not only new muscle fibres, and in the spine and brain motor cells which dominate and execute these movements, but also creates in the central nervous system false motor paths which transmit the motor impulses for the crippled movements.

By this I do not mean to imply that the vicarious movements and the activity of the auxiliary muscles are in themselves detrimental. They are, on the contrary, conservative processes. The vicarious movements are the substitute for the direct movements which save the paralytic from total helplessness. They are Nature's crust. The activity of the auxiliary muscles is Nature's tendon transference, so much superior to surgical tendon transference. The tendon transferred by surgery must give up forever the function for which it was originally destined before it can take up the new burden, while in the case of auxiliary muscle activity the tendon learns to perform the work created by the paralysis without interfering in any sense with its original mission. Where there is a total paralysis of a group of muscles, therefore, these two vicarious processes should even be encouraged. For the patient will need the crutch permanently, and the stronger it is made the greater its service to him. But, as a rule, there is paresis, and not paralysis. To teach the patient to use the paretic muscles and to persist in using them, to help him to unlearn the use of the vicarious movements which stamp him a cripple, is the aim of muscle education.

Healthy muscle responds quickly to exercise, and therefore comes the temptation to use gymnastics. (The term gymnastics is here used to designate simple exercise, the brunt of which falls mainly on the auxiliary muscles in infantile paralysis, while the term muscle education is reserved to the scientific application of the exercise by which the paretic groups are mainly compelled to function.) The temptation to use gymnastics is increased by the fact that the exercise of the auxiliary muscles generally improves the patient. But as was explained before, this is the wrong kind of improvement, and, on the other hand, paretic muscles respond slowly to exercise. Therefore muscle education is tedious, and often disheartening. Yet the response of paretic muscles to exercise is unquestionable, and the tediousness itself is felt only at the beginning. Later, when the paretic muscles begin to gain in strength, there is a great deal of encouragement. The gain may be small, but it is of the right kind, for it is due to the improvement in the patient’s pathological condition, and not to mere development of vicarious muscle strength, which, though making the patient’s movements firmer, eventually does him harm.

We must remember that the only thing that will stop the conversion of muscle cells into fat or fibrous cells, a process going on continually in the paretic muscle, is voluntary functioning of the
affected muscle. According to the investigations of D. Koch, voluntary functionating of the paretic muscle has even the power to regenerate a great many of the muscle cells in the fatty areas which are distributed throughout the paretic muscle. However, we do not need any theory to convince us of the superiority of muscle education over gymnastics. I know many patients who for long periods were making little progress under treatment, but who gained rapidly when the more scientific exercise was introduced. Muscle education takes advantage of the law of compensation, by which surviving cells take over to themselves in a measure the function of destroyed similar cells, as in the case of increased hearing or vision in the remaining ear or eye when one of the organs is destroyed. In poliomyelitis the law of compensation expresses itself by the surviving part of the affected motor cell taking over to itself some of the burden of that part of the motor cell which was destroyed by the infection. The theory has also been advanced that in some cases the motor cells of the opposite side of the cord come to the rescue and take over some of the function of the destroyed motor cells. The two halves of the spinal cord and the motor cells on each side are interconnected by innumerable fibres, which makes an occurrence of this kind possible. Muscle education is the unique measure in the therapy of chronic infantile paralysis which influences the lesion itself, for it tends to develop the remnant of power left in the crippled motor cells, while all other measures deal with muscles, nerves, bones, etc., structures remote from the seat of the lesion itself.

The success or failure of all other measures is also dependent directly upon muscle training. For instance, persistent aftertreatment, the chief element of which is exercise, must follow the operation for tendon transference. So vital is the aftertreatment that many of the failures of this operation are attributed directly to the lack of aftertreatment, or to the unscientific application of it. The same is true of braces. They assist locomotion, but they have an inhibitory effect on the muscles. The only way to combat this inhibition is by muscle education. The substitution of muscle education for gymnastics would result not only in greater improvement from treatment, but in fewer failures in the operation of muscle transference, and in better results from the sometimes indispensable but always harmful brace.

TUBERCULOSIS IN THE UNITED STATES ARMY:

A Study of the Admission Rates for Seventeen Years.

By ISAAC W. BREWER, M. D.,
Taughannock Falls, N. Y.

In the United States the active campaign against tuberculosis may be said to have begun with the formation of the National Association for the Study and Prevention of Tuberculosis in 1904. Prior to that time much educational work had been done by Trudeau, Biggs, and others. During the past seventeen years there has been aroused a great deal of enthusiasm regarding the prevention and cure of the disease, and some of the most enthusiastic are predicting the conquest of the disease in the near future. The president of the local antituberculosis society in Manila adopted the motto, "No tuberculosis in the Philippines in 1920." Those of our fellow workers who are so much encouraged base their belief upon the published death statistics, which in most instances show great reduction in the rates charged to tuberculosis. However, death rates do not tell the entire story, for by modern methods of treatment we are curing many who would have been numbered among the dead but a few years since. While from the individual standpoint it is highly desirable to cure as many of these persons as possible, if we do no more we are in the long run failing in our endeavors to conquer the disease, for the cured patient is at best a cripple.

The correct judgment of the results of the campaign against tuberculosis must be based upon the number of persons taken sick and not upon the number who die. Statistics of morbidity are difficult to obtain and are generally untrustworthy. However, in the United States army there are fairly accurate records of the numbers of men taken sick and the causes of sickness, and from these we may form some idea of the results obtained from our efforts at prevention. I have therefore collected the published statistics from the annual reports of the surgeon general of the army from the year 1885 to 1911, and here present them as showing the morbidity from tuberculosis amongst picked men. It is assumed that these statistics are fairly accurate, and that the conditions

![Chart 1](chart1.png)

![Chart 2](chart2.png)
among the civilian population of the country will not be as good, because all of the men entering the army are carefully examined, and all of those with symptoms of disease rejected, especially if there is any deformity of the chest or lack of chest mobility. The soldier is, in addition, well housed, well fed, and not overworked. The sanitation of his environment and his personal hygiene are carefully supervised by the medical officers. All cases of disease, with but very few exceptions, are treated in the hospital, and no case of tuberculosis or other infectious disease is treated in the barracks. It will therefore be apparent that the soldier’s chances of becoming infected are much less than are those of the general public.

The statistic here presented are subject to the allowance that must be made for data gathered by many individuals with different personal equations. It may be inferred that in recent years the diagnostic acumen of the medical officers has become more acute, but it is believed that this has not had any great effect upon the statistics. Tuberculosis when wrongly diagnosed is called either fever, malaria, bronchitis, or influenza. An examination of the statistics at the different posts where I have served does not seem to prove that this has made any appreciable difference in the statistics. In the army, with rare exceptions, a case of tuberculosis, no matter what the original diagnosis was, will sooner or later appear under its proper classification. Occasionally a man may be discharged without a correct diagnosis having been made, but this is very rare. During the past five or six years greater care has been taken in the examination of recruits, and therefore a greater number of latent cases must have been excluded. The statistics here presented show that for the ten years ending with 1894 the average admission rate for tuberculosis of the lungs was 3.24 in a thousand. There was a decline in the rate until it reached 1.59 in 1896. With the advent of the war with Spain the rate ran up to 3.70, increasing to 4.92 in 1900. By 1903 it had fallen to 3.89, but up to and including 1907 it remained above four in a thousand. In 1908 it fell to 3.81, but there was a slight rise in 1909, followed by a marked fall in 1910, when the rate of 3.12, the lowest since 1896 was reached. During 1911 there was a slight rise.

A study of the curve for the general admission rate for all diseases in the army shows that it rose rapidly during 1898 and 1899, but that it has fallen continuously since that time. The rise in the rate for pulmonary tuberculosis was somewhat slower, reaching its crest in 1900, and the amplitude was much smaller. The decline has been smaller, and whereas the general admission rate has now fallen below that of 1906, the rate for tuberculosis is considerably above the rate for that year.

Similar conditions are found in the statistics for the navy. The surgeon general of the navy, in commenting upon these, says that the incidence of tuberculosis corresponds very closely with the strength of the navy, and that this is due to the enlistment of those previously infected. I have considered the rates in the army in this connection and find that there is no coincidence between the two. Neither does the data at hand seem to prove that there is any connection between the curve for recruits attacked during the first year of their enlistment and the general curve.

The rise for admission to the United States Army has not been accounted for by the increase in the yield of the navy, as the latter returns a lower rate of admission for cerebral and nervous diseases. The causes of the rise are evidently due to the greater accessibility of the soldiers to the general population, and to the increase in the number of the army as a whole, which has risen from 128,000 in 1894 to 412,000 in 1909.

The following table gives the average admission rate for tuberculosis for the years 1895-1904 and the rate for the year 1905:

CAUSES OF CRIME.*

By Paul E. Bowers, M. D.,
Michigan City, Ind.,
Physician in Charge, Indiana State Prison.

The question of the cause of crime is one of the most serious and difficult problems with which society has to contend. Concomitant with the advances made in civilization, there has been an increase in the kinds of crimes and the number of criminals. The law of the fittest has ever been enforced, but the surviving qualities have constantly changed and evolved. The physical struggle for supremacy of the past primitive ages which has been transformed into the present day struggle for existence, is, however, none the less determined and aggressive, even though there has been a refinement of methods. To-day it is mind against mind and brain against brain, and as a result of the demands made upon the central nervous system we find that one out of every three hundred persons in the United States is insane, and that one tenth of one per cent. are housed in penal institutions.

Over one million of dollars a day is spent in society’s efforts to stem the criminal tide of degeneracy that bids fair to submerge us, and in spite of the claims of enthusiasts, our prisons are full to overflowing. This problem being so paramount, what measures shall be taken to protect our civilization? The matter of treatment will not be hard to determine when we have, with scientific exactness, determined the cause of this foul sore on the body politic.

*Read before the Logansport Presbytery, April 13, 1913.
It has been recognized only within recent years that vast quantities of clinical material are going to waste in most prisons for the lack of scientific investigation on the part of qualified investigators, who would shed a flood of light on the criminal question. Owing to the limits of this brief paper I will classify the causes of crime under two great heads:

1. External, or environment causes,
2. Internal, or constitutional causes.

By the external or environmental causes we mean those forces which are brought to bear outside the criminal himself, which act against him throughout the whole period of his life, such as opportunities for securing food, clothing, and education, existing economic conditions, and the conventions of social life.

As to internal or constitutional causes, these forces must be looked for within the criminal himself, in his prenatal existence, with its burden of heredity and its tyranny of ancestry, in his physical, mental, and moral organizations. Before going further I will read a tabulation of 2,681 consecutive admissions to the Indiana State Prison, where criminals over thirty and murderers are receiving. I found that out of this number, 2,293 prisoners had used alcohol, eighty-three per cent. of the latter had used intoxicating liquors to excess, getting drunk at frequent intervals, 1,362 admitted that they had been infected with gonorrhea, 476 admitted infection with syphilis, and we can safely surmise that nearly as many more had been infected, but denied their venereal history; 127 admitted the use of narcotics, 1,878 had been previously convicted of criminal offences. This last fact shows a clear mental defect, namely, a lack of inhibitory control. One hundred and fifty-three had been convicted of rape, forty-three had been convicted of sodomy, and forty-six had been convicted of incest; making a total of 242 convictions for perversion and invasions of the sexual instinct. Pedestrians by no means uncommon among the recidivist and habitual criminals. One hundred and twelve were actively insane at the time of admission, forty-seven were epileptics, 596 were classified as dull, nearly fifty as feebleminded of varying degrees, and 622 had relatives who were insane, feebleminded, or epileptic.

I will first discuss somewhat in detail the external causes.

**ECONOMIC CONDITIONS.**

The continuous and bitter struggle between capital and labor has a most disastrous effect upon the public. The financially weaker members of society are the first to suffer the dire effects of this never ending strife. The strength of the poor is undermined and devitalized by the sweat shop systems, which employ women and children at a wage insufficient to buy food and clothing. When the time for parenthood arrives, the reserve strength, vitality, and stamina necessary for healthy reproduction are lacking, and therefore many children are born into environments where poverty and ignorance are the only legacy. In our rich and well to do classes, luxurious idleness, conventional debauches, and the continuous round of excitement, to appease a hysterical and unsatisfied craving for novelty, are among the causes which operate to produce crime and criminals.

**EDUCATION.**

If a child escapes with its life the infantile period, education is not always provided, for commercialism often transforms the childish minds and bodies into sickly and defective derelicts. Even should an opportunity for education be assured and thereby highly developed wants and desires be created, a spirit of anarchism is produced by the economic conditions that do not permit of their satisfaction. We have abundant testimony of this last fact in strikes, bloodshed, and serious outbreaks against the law. Our present standards of pedagogy contain many frills which should be eliminated; more attention must be paid to vital subjects, like hygiene and physiology, including that of sex, instead of leaving this teaching in the hands of the vicious elements of the street. The theatre, which performs so great a function in the education of the public, has been betrayed for thirty pieces of silver. Licentiousness runs riot on the stage, and even the modern problems plays are baited with juicy bits of sensuality to form a bacchanalian feast for the eyes and imagination of the adolescent girl and boy: and these all lead to sexual crimes or those allied and dependent upon kindled sexual excitement. Bad companionship and vicious associations which foster idleness, frivolity, and excessive love of pleasure constitute one of the most potent contributing factors in the production of crime. Intemperance, as we all know, is a most prolific source of offense against physical, moral, and civil law. The growing lack of proper regard for moral and religious teaching sows a seed for the disrespect for laws which are consequently broken. Many practices of the business world are exceedingly questionable, and often have I heard this referred to by prisoners in a jesting manner, who remarked that if their crime had been the theft of thousands of dollars, instead of ten dollars, they might be respected and honored as elect and influential members of society.

There has been a vast increase in the number of murders in recent years, largely due to the sickening, mawkish sentimentality which would abolish capital punishment, and therefore increase a disregard for human life. Even darkest Italy has far less murders than the United States, which so shamefully heads the list in this regard. "There were 1,500 homicides in the United States in the year 1886, and more than 8,000 in 1911, an increase of 500 per cent., allowing for the increase of population. There were twenty-six homicides for every 1,000,000 of population in 1886, and eighty-eight for each million in 1911. It is a most threatening fact, therefore, that we have reached great altitude in crime, and we are with only trifling variations maintaining this alarming level year after year. Murder in Michigan increased from sixteen, in six years prior to abolition of hanging, to 152 in the same period of time, after forty years' trial of abolition; an increase of 2,500 per cent. Iowa, Colorado, Rhode Island, and Minnesota have restored the life penalty after experiencing a period of an-
archy and murder. I have failed to see as yet any enthusiastic advocate of the abolition of capital punishment who would not take life if such a course were necessary in defense of his own; his plea would be self preservation, and yet how much more necessary is the social defense than his right to protect his own little insignificant and selfish existence.

INTERNAL CAUSES.

I shall now briefly consider the internal, or constitutional, causes which are potent for the production of crime. Those of us who are familiar with abnormal as well as normal psychology know that at least fifty per cent. of the inmates of our penal institutions are composed of mentally and physically defective individuals, whose organizations preclude the possibility of their adjusting themselves to the conventions and laws of society; and unless we appreciate this fact much of our effort for reformation will be useless, for the defect can never be remedied. The doctrine of inherited degeneracy is in many respects a cold and heartless one and it has oftentimes been refuted for sentimental reasons; but much of the skepticism concerning this doctrine will be dissipated after a careful and systematic study of many criminals. A classic example and proof of inherited social degeneracy is the history of the Jukes family, which descended from the infamous Margaret, the mother of criminals; and for the sake of comparison I will read the following table which appeared in the Medical Record:

| Margaret Jukes (born, 1720) — 1,200 descendants identified | 300 in the poorhouse; 440 viciously diseased; 300 died in childhood; 400 physical wrecks; fifty notorious prostitutes; seven murderers; sixty habitual thieves — averaged twelve years in jail. |

Hereditary is fortunately not always degrading, as may be seen by the worthy transmission to posterity by Jonathan Edwards.

Jonathan Edwards (born, 1703) — 1,394 descendants identified; 205 college graduates; one vice-president; three United States senators; twelve college presidents; sixty-five college professors; sixty physicians; one hundred clergymen; seventy-five army and navy officers; sixty prominent authors, one hundred lawyers, eighty public office holders.

Many persons are now serving sentences in prisons whose crimes were merely symptomatic expressions of disregarded or unsuspected mental disorders; at least five per cent. of the admissions to our penal institutions belong to this class — our justice is often so confused, obscure, and tangled by the technicalities and faults with which our legal system bristles that the insane and mentally irresponsible must bear the stigma of being criminal. Again, there is a class of individuals who are necessarily abnormal, but whose abnormalities we are slow to conceive, because in so doing we seem to fiercely challenge the belief of man’s free will; for only in this idea do we see permanence and stability of our present system of government and theology; but under the guiding fingers of psychiatry no alarm need be entertained, and we do find clinically again and again that there are individuals who are born with a defect of the moral sense in the same manner that some individuals are born without the ear for music or harmonies of sound or that others are totally devoid of the sense of color. These unfortunate individuals are “as flowers without perfume and dogs without scent,” and from the very nature of their constitutions they must be continually at war with the conventions and morals of ordinary society. They can, in general, assent to the abstract proposition of right and wrong, and they may delight to exploit their powers of language and casuistry to confuse and deceive those who are unaware.

ANTHROPOLOGY.

Anthropology has thus far failed to establish a distinct criminal type, but marks of constitutional inferiority are exceedingly common in prison populations. Among the anatomical defects are to be found malformations of the skull, teeth, and palate, the Darwinian tubercle, and Morell ear and prosathism; all of which may be interpreted to mean reversions to more primitive types. These same evidences of stigma are, of course, frequently found in normal individuals, but they so often appear in our defective, dependent, and delinquent classes that they may be considered as marks to distinguish the normal from the abnormal, and they at least suggest the causes which produced corresponding defects in the psyche. The physiological abnormalities encountered are perversions of the sexual instinct, uncontrollable desire for liquors, migraine, disorders of the nervous system, insensibility to pain, defects of speech, and reduced physiological tension. The psychic stigmata are more clearly defined here; we find exaggerated egoism, eccentricities, ill balanced mental activities, irritability, inability of continuous application to mental or manual labor, emotional poverty, brutality, and fatalism. Disagreeable as it may be, we are nevertheless forced to believe that criminality rests as much upon a biological as a sociological basis, and unless we combine medical care with our mental and moral instruction, our efforts will be in vain.

RELIGION OF CRIMINALS.

Out of 10,538 prisoners admitted to the New York State Reformatory at Elmira, N. Y., only 246, or 2.34 per cent., failed to profess any religion. Convicts as a whole are professors of religious faith, and I have found the following classes from personal study:

1. Chronic offenders of the law or veterans in criminality who profess religion to impress their keepers with an idea of reformation.
2. There is a class of prisoners who resort to religious exercises and professions of faith to secure a moral narcosis to appease emotional instabilities and the wanderlust of their superstitiousness.
3. The third class is composed of those individuals who are normal men and who earnestly and sincerely seek a reformation in character. This last class is sadly in the minority.

We must cease the manufacture of idiots, of epileptics, of insane and criminally predisposed persons, in the name of humanity. We must cease to permit the debauchery of the innocent, we must prevent the marriage of the syphilitic rout with the chaste virgin, the tuberculous with the tuberculous, the insane, the epileptic, and the degenerate
DIABETES MELLITUS.

Treatment with Bacillus Bulgaricus Cultures.

By J. Wallace Beveridge, M.D.,
New York.

(Concluded from page 76.)

Case VII. Mr. A. H., aged thirty-five years, married. Weight 175 pounds; greatly emaciated; slightly neurotic; mental state of anxiety; head full; appetite poor; coffee and tea six to seven cups daily; complained of severe headaches, malaise, severe thirst and loss in weight, cramps in the calves of legs; pulse 100; blood pressure 160; heart, mitral regurgitation; weight 137 pounds. Treatment: Bacillus bulgaricus, two tubes three times daily; pancreatic ferments; diet modified; began to improve at once; seen January 27, 1912; weight 143 pounds; urine voided in twenty-four hours, sixty-one times; all apparent symptoms had disappeared; appetite good; slept well; able to do her housework; sugar still present; discharged.

Case VIII. Mr. W. B., aged forty-one years. First seen July 27, 1912. Tall; thin; weight 154 pounds; slightly neurotic; mentally high; slept well; appetite good; constipated. Urine, amount increased; 100 ounces in twenty-four hours. Family history negative. Rheumatic attack three years previous; fever; age of eighteen; indigestion during last three years; kidney, diabetic condition three years; refused by insurance company. General physical condition heart; somewhat decreased; pulse 72; blood pressure 120. Treatment: Sodium bicarbonate, five grains every four hours; two tubes Bacillus bulgaricus daily, then increased to three tubes; modified diet. September 7th, weight 138 1/2 pounds; condition good. September 21st, weight 160 1/2 pounds; on general diet.

Case IX. Mr. C. B., aged fifty-seven years, married. First seen July 26th. Stout; pendulous abdomen; weight 194 pounds; slightly neurotic; mentally high; slept well; appetite good; constipated. Urine, amount increased—115 ounces. Family history negative. Rheumatic attack five years previous; malaria for seven years; diabetic condition known two years. Heart: normal; liver, hypotrophied; lungs, chronic bronchitis; stomach dilated; arteries soft; pulse 79; blood pressure 145. Treatment: Modified diet; three tubes of culture daily, then one tube; sodium bicarbonate, five grains every four hours. Last seen November 16th. Diet regular; condition normal; discharged.

Case X. Mrs. L. A., aged fifty-six years, married. First seen September 10th. Short, stout, pendulous abdomen; neurotic; slept poorly, arose two or three times to void urine, urine greatly increased, 120 ounces; bowels regular; appetite poor; coffee and tea six to seven cups daily; complained of severe headaches, malaise, severe thirst and loss in weight, cramps in the calves of legs; pulse 100; blood pressure 160; heart, mitral regurgitation; weight 137 pounds. Treatment: Bacillus bulgaricus, two tubes three times daily; pancreatic ferments; diet modified; began to improve at once; seen January 20, 1913; weight 143 1/2 pounds; urine voided in twenty-four hours, sixty-one times; all apparent symptoms had disappeared; appetite good; slept well; able to do her housework; sugar still present; discharged.

The urine analyses were made by the Bendinder and Schlessinger Laboratory and the Higgins Laboratory. The blood examinations by Dr. J. C. Welch and the Higgins Laboratory, and the stomach contents' examinations by the Higgins Laboratory.

The patients under observation might be divided into two great classes, the glycosurics without acidosis and the glycosurics with acidosis.
Glycosuria without Acidosis (First Class).—During the early period or onset there may be a total absence of any classical sign which would direct either the patient’s or the physician’s attention to a beginning glycosuria, unless, perhaps, discovered by an urine examination. These patients may go for a considerable length of time without noticing any untoward symptoms, possibly complain a little of constipation, heartburn, or indigestion after eating. Then, as the disease progresses, a severe shock such as worry, exposure, overindulgence, or a rheumatic attack will cause the first unpleasant symptoms to appear, which are generally described as weakness in the legs, cramps in the calves and knees, loss of weight, polyuria of varying intensity, pruritis, a sense of burning when the urine is passed, constipation, indigestion, headache, ach, impaired vision and hearing, dryness of the skin with brittleness of the finger nails, and falling out of the hair. These symptoms may gradually increase in severity, while in others the tolerance for considerable quantities of sugar is acquired with the subsequent abatement in many of the unpleasant physiological reactions. The patients who do poorly are the ones who lose weight rapidly, and the sugar index continues above five per cent. Such patients should be placed under strict observation and a special effort made to prevent the loss of weight and the continued excessive production of sugar; otherwise, at any moment a severe acidosis with coma may involve the patient.

Glycosuria with Acidosis (Second Class) should be divided, for convenience, into three stages: those with acetone, those with a trace of acetone and diacetic acid, and those with marked acetone and diacetic acid, a condition always accompanied by the production of beta oxybutyric acid. The symptoms in this class are similar to glycosuria with acidosis, but the increasing weakness and malaise are more pronounced. One symptom always present is drowsiness, while vertigo and headache, if accompanied by other indications of digestive disturbance, such as vomiting, obstinate constipation and severe heartburn, or by acute gastritis, are always forerunners of grave sequelae which often end in coma. If seen before the disease has advanced to a degree in which the involvement and systematic changes have become so great that nothing can be done, patients will, as a rule, readily improve under treatment. The patients observed range from nine to seventy-four years in age and the cases include glycosurias from those with very small amounts of sugar up to the most severe types of acidosis with dropical effusion.

The treatment of diabetes requires more time and consideration on the part of the physician than most diseases that come under his care. The difficulty of keeping the patient upon a strict diet and making him understand the necessity for following any good therapeutic procedure is almost insurmountable, because the moment diabetic patients begin to feel an improvement or notice the symptoms disappearing, the desire to eat forbidden food and do things that are inadvisable seem to overcome their better judgment and they submit to these inordinate desires. The cases under ob-
servation are divided, as already indicated, into two classes. The first class present the widest field for scientific work, especially by preventing this disease from a progressive development. Chronic constipation with intestinal putrefaction is the major difficulty encountered requiring correction, and a systematic examination should be undertaken to determine whether the intestinal tract, through a mechanical fault, or a chemical derangement during digestion is responsible for the condition. This we do first by an analysis of the stomach contents after a test meal and by examination of the urine and feces. The intestinal tract is then radiographed and a general summing up made of what

may be wrong. Knowing the fault causing intestinal putrefaction, our efforts are then directed toward giving relief. Should this condition be due to gastric or liver inactivity the accepted drugs are given, with from four to six tubes (equal to twelve or eighteen centimetres) of the bulgaricistic culture each day. The action by this culture, as shown, begins at once to stop intestinal putrefaction. The culture is continued until an indican free urine has persisted for five weeks, then the culture is gradually diminished until one tube (three c.c.) every other day suffices. Not until every trace of sugar has been absent from the urine for a period of three months do we entirely discontinue using the culture. The mechanical defects, unless very serious, may be greatly aided by abdominal exercises, daily massage, and the galvanic current. In ptosis, always seen when the patients are obese, with pendulous abdomen, special braces and supports should be worn.

It is necessary to ascertain in the very beginning what the carbohydrate tolerance of each patient may be, and then, by a gradual increase of starch in the daily diet we find exactly what the capacity for the daily production of sugar during the twenty-four hour elimination is. If the carbohydrate tolerance is fairly high and the percentage of sugar indicated in the urine analysis moderate, a liberal diet is permitted, consisting of cereals, oat meal and rice, together with the following: Fruits—apples and grape fruit; meats—chops, bacon, ham, roast beef, lamb, chicken and turkey; fish—only fresh fish; vegetables—salads, tomatoes, cucumber, endive, lettuce, celery, cooked spinach, tiny Lima beans, baked potatoes, every other day, and string beans; bread. The prepared flours are mostly untrustworthy. The one most acceptable is the jirah, but we have suggested using crusts of plain French rolls and toasted bread, permitting three or four slices daily. Desserts: These may be prepared with a little sugar, enough to just sweeten; the most nutritious are cup custard, junket, and jellies made from gelatin. Liquids: One cup of coffee or tea, buttermilk; no beer under any circumstances. Cheese: Unfermented, such as American and Swiss cheese. This diet may be added to from time to time as the patient's condition warrants. The alimentary tract should never be overloaded and the peristalsis must be watched. The use of the cul-

Acid. But a beginning acetonuria should never be allowed to advance so far as to permit acidosis. If the patient is under control and follows suggestions made acidosis is preventable. The abolishing of carbohydrates from the diet is one of the principal factors in the cause of acidosis. We may be able to greatly diminish the percentage of sugar, but by so doing the changed metabolism of the cell, owing to the absence of carbohydrates, increases the possibility of acidosis. Should acidosis be present we place the patient upon a fluid diet, insisting on milk, clear broths, and fruit juice, suggesting that they remain in bed during this in-
terval for about three weeks. A culture of the Bacillus bulgaricus is given up to twenty-four c. c. per day. Sodium bicarbonate or calcium chloride is also used, and if patients complain of great weakness quinine dihydrochloride (which comes put up in ampoules of one c. c., equalling three and three-quarter grains) is injected subcutaneously once every twenty-four hours for a period of ten days. Should the patient be inclined toward obesity the glandular extracts are indicated. The patients so treated responded favorably, losing all signs of acidosis, unless the disease had advanced to such an extent that the involvement had caused marked emaciation and changes in the viscera. Then medicinal treatment was without avail. Exercising or any severe muscular exertion is apt to bring on acetonuria. Seemingly, the rapid breaking down of the muscle cell has a direct bearing upon the formation of acetone bodies. Acetonuria and acidosis may be present in other diseases with intense metabolic changes and is observable in infants suffering from inanition, as in marasmus. The diet permissible following the initial regime in allowed cases of acetonuria without acidosis, is the same as the modified diet for the simple glycosurias, with the exception that no meat is permitted. Great care must be taken that all these patients receive sufficient nourishment and do not lose weight, otherwise trouble will begin.

Complications are treated as they arise, but unless the patient presents serious complications in the very beginning they should not be permitted to occur. We have seen seven cases of carbuncles, one demanding incision, the others clearing up after treatment. In gangrene the usual surgical methods are best.

Prognosis.—In cases of the first class the symptoms entirely subsided during treatment. Only seven still have traces of sugar and if they are kept under observation from time to time I believe will remain in a fairly normal state. In cases of the second class the results have not been so marked, although all the patients have shown considerable improvement, with most of the major symptoms disappearing. The gain in weight has averaged from three to eighteen and a half pounds, and in many the polyuria has diminished from eight quarts a day to three quarts and one pint. The proportion of recoveries, however, is very small, and out of seventy-nine cases of acidosis we would say that five have recovered and twenty-seven have apparently been greatly benefited; the rest, with the exception of two, remaining about the same as when first observed. These two patients, both under fifteen years of age, have since passed away.

Conclusions.

1. The efficacy of this culture in diabetes is undoubtedly due to its power to prevent intestinal putrefaction.
2. The stimulating effect upon the pancreas by its acidity is potent.
3. Its power to convert starch into lactic acid is an imported factor.
4. By relieving auto-intoxication many of the symptoms in diabetes are stopped.
5. The use of the x ray in diagnosis is most valuable.

6. The necessary analysis of the gastric contents should be made so a consistent method may be followed in treatment.
7. The routine examination of the blood, not only for acetone, but sugar, is advisable.
8. The prevention of this disease and the overcoming of its progress is unquestionably possible, and I believe by systematic, thorough care of all glycosurias in the first class a permanent recovery will be the reward.
9. Glycosurias of the second class do not apparently respond, although the patient's condition seems to be greatly benefited.
10. The use of this culture in diabetes is far superior to that of opium and offers the only rational internal therapy really of value.

7 East Thirty-eighth Street.

WORK OF WOMEN IN DEPARTMENT STORES.

By Josephine Goldmark

Publication Secretary of the National Consumers' League.

To most persons the employment of women in department stores does not seem to involve exposure to disease, as in other occupations where the workers are subjected to poisons or extremes of temperature. To many, indeed, the work of women in department stores seems like a pleasant occupation by which many young women, while they live at home, are earning pin money, which enables them to buy comforts or little luxuries in which they might not otherwise be able to indulge.

The number of women and girls employed in this city and State in the department stores amounts to many thousands. It is true that in many respects these women and girls have better physical care than other workers. Many of the large establishments have fine rest and lunch rooms, and in some there is a hospital room where medical care is provided free of charge. But, in spite of these remedial measures, the employees of department stores suffer from the same evil as working women in other occupations—an evil which, unless guarded against, becomes in a short time an unmistakable danger to health. This evil is the simple physiological factor of fatigue, well known to all of us. Everyone knows what it is to be weary, to be fatigued at the close of the day, and the standing wonder is that after the night's rest nature has so ordered that we arise refreshed and ready for another day. How does this happen? In its normal form fatigue is of course not a danger to health. It is the perfectly natural result of all activity. Fatigue is rather nature's warning signal, and when the signal is disregarded overfatigue and exhaustion result, and health is threatened.

Now, during the past half century this phenomenon of fatigue has been studied in detail in the laboratory by scientific men and physicians. We must remember that in the living body two pro-

*Prepared at the request of the Committee on Public Health Education of the Medical Society of the County of New York and read under its auspices at a public meeting held at the New York Academy of Medicine, January 22, 1913.
processes are continually going on. Physiology teaches that life is a continual change of structure. The life of all tissues consists in chemical combinations of the substance of the tissue cells with the nutritive material derived from food and the oxygen of the air. Two processes are continually carried on: Building up, or assimilation, and dissimilation, or the breaking down of material into simpler chemical forms which are ultimately expelled from the body as waste products. More than forty-five years ago, in 1865, the German physiologist, Ranke, first investigated the action of certain chemical products of muscular action. He showed, for instance, that if an extract of fatigued frog muscle were injected into a second frog, the muscles of the second animal showed evidence of fatigue. About twenty-five years later, the Italian, Mosso, showed that the blood becomes charged with these chemical waste products in the muscles and carries them to all parts of the body. He proved this by injecting the blood of a dog fatigued by long running into the blood vessels of a second dog. Upon this the second animal showed all the usual signs of fatigue. The study of muscular fatigue has been studied in the laboratory in great detail and the general results have proved that in muscular fatigue there are three general stages. During the first stage the activity of the muscle increases more and more. This is known to physiologists as the tredpie, or staircase. Then the highest point of activity is reached, and after a while the activity of the muscles begins to diminish. These three stages of fatigue, shown in the laboratory experiments, are well known to all of us. Everyone knows that in most work there is a first stage of “limbering up.” Then we gradually reach the plane where our working power is at its best, until fatigue inclines it unmistakably downward, and our powers begin to flag. If then we continue to work after real fatigue has set in, our task, whatever it is, becomes more and more difficult. We need a greater and greater effort of will to keep up what we may have done easily before.

Now, all this may seem to take us far away from the girl in the department store, or the girl in the box factory, or the girl who is packing candies until midnight before Christmas, or doing any of the innumerable things in which women are employed in industrial life. It is indeed extraordinary that, until practically within the last few years, all these facts concerning fatigue and exhaustion and their effects, which were studied in detail in the laboratory, have been so largely ignored in the many efforts made in all countries to protect working women against excessive exertions in industrial life, detrimental to their own health and vitality and to that of their future children. It has been uniformly found by all civilized nations that the only practicable way for a community to protect the health of its women workers from overwork and exhaustion is through the action of the State, by uniformly prohibiting more than a specified number of hours of work in one day and in one week. Labor legislation for women is no new subject. One hundred years of experience have elapsed since the first factory acts were enacted in England, almost a century ago, and in our own country Massachusetts led the way by the first ten hour law for women, more than a generation ago, in 1874. Yet to-day similar measures are still being successfully opposed in many of our States. The knowledge accumulated by the scientists in regard to the nature of fatigue and the physiological necessity of rest has been too little applied to the prevention of overfatigue and exhaustion in industrial pursuits. If it is necessary to have rest to balance exertion in order that our organism may repair itself from day to day, then such rest between working days is most imperative for people who are subjected to the strain and rush of employment in modern industry. It is therefore imperative that the day's work in factories and stores alike be limited by law, and here we face a surprising fact in New York State. The New York law provides that women may not be employed in factories more than ten hours in one day and fifty-four hours in one week; but for adult women in department stores there is no legal limitation of work whatsoever. New York is almost the only great industrial State which thus discriminates against the girls and women in department stores. In twenty States of the Union the law governing factories governs employment in department stores also. Three States (California, Colorado, and Washington) prohibit more than eight hours' work in one day; other States like Illinois, Louisiana, Kentucky, Maryland, Michigan, Wisconsin, and even our neighbor New Jersey, prohibit more than ten hours in one day. New York provides a limit only for girls under twenty-one years; and, since no proof of age is required, this law is practically impossible to enforce. The consequence is that, as a recent government report on wage earning women in department stores shows, women are employed up to fifteen hours in the day in department stores. Detailed statistics of the hours prevailing at rush seasons in department and retail stores are given in the report of the New York State Factory Investigating Commission, just published. This investigation of department and retail stores covered 216 establishments, employing over 40,000 women and children. The ordinary hours were not long—being under fifty-seven hours in one week; but at Christmas time and in preparation for the holiday season, the hours are greatly lengthened. For instance, in sixty-six large department stores in New York city the employees worked the following hours during the six days preceding Christmas (December 18 to 24, 1912), including Sunday:

In 16 stores there was no overtime (i. e., store closed at 6 p. m.).
In 3 stores the hours were from 60 to 65.
In 5 stores the hours were from 65 to 70.
In 4 stores the hours were from 70 to 75.
In 20 stores the hours were from 75 to 80.
In 18 stores the hours were from 80 to 85.

These are actual working hours, as the time off for luncheon and supper has been deducted. In addition to these excessive hours during the week, girls in certain departments worked also on Sunday, December 24th, varying from five to eight

---

hours. In twenty-eight five and ten cent stores the hours (from December 18 to 24) were as follows:
In 3 stores there was no overtime.
In 1 store the hours were from 65 to 70.
In 12 stores the hours were from 75 to 80.
In 12 stores the hours were from 85 to 90.

Of the effect of these extremely long hours, continuing until late in the evening, the commission says:

There is scarcely a salesgirl who does not complain of the extreme lassitude and lessened power of work experienced as a result of this exhausting toil. From Thanksgiving to Christmas the pressure of work is cumulative. From day to day the crush in the store increases, and the demands upon a girl's time and attention grow more insistent and unremitting. The air of the store is vitiated. There is rarely a moment to sit down and relax. At lunch time comes the only break, and, in the overcrowded condition of most stores, a girl may have to stand in line ten minutes out of forty-five before she can get her luncheon, though her feet may be aching cruelly from long hours of standing. She may thus lose part of her short noon period for recuperation. Moreover, she must return to her counter strictly on time under pain of fine for lateness, no matter what the delay in the lunch room. At 6 p.m. nervous endurance has ebbed, and the tension of added evening work strains the physical and nervous powers almost to the breaking point. Girls ordinarily in good health complain that after the late return home their sleep is broken and unrefreshing. If a girl lives at any distance from the store her night rest is cut down, since she may reach home after 11 p.m., and yet have to return to her post at 8 or 8.30 the following day. Finally, when the rush is over, Christmas Day is often spent in bed, and for weeks thereafter the ill effects to health are still felt. According to the testimony of physicians, subsequent slack time cannot repair the inroads upon health due to such extreme overfatigue.

The discrimination against the women employed in stores is the more unreasonable because the strain of their work is being more and more clearly recognized. It is true that they are not subjected to the speed, monotony, and complexity of machinery, but the girl behind the counter suffers greatly from the constant standing, continuing at any rush season literally throughout the day. Many girls complain of broken arches and varicose veins. There is also a great nervous strain in being always on one's good behavior, and of an even temper, suiting the tastes and whims of customers. She needs the protection of the law as urgently as the factory worker to safeguard her health. Physicians agree that injuries to the female organs result from such long hours of standing, and that they may injure a woman permanently for life.

The report of the government on the earnings of saleswomen also disposes of the theory that this is pin money work and that wages may therefore be very low because they are not actually needed. The report shows that the overwhelming majority of the girls who were studied in department stores handed over all their earnings toward paying the family expenses. They were helping to support families in which the father was either not earning enough to support his wife and children or in which there was no male bread winner. Only 3.7 per cent. were pin money workers.

The same fact was shown in Boston, where a detailed study of women employed in department stores was made by a State commission last winter. There, too, out of 3,000 girls only 3.3 per cent. pin money workers were found. From among 3,000 girls and women whose cases were studied ten per cent. averaged less than $5 a week, and thirty per cent. less than $6 a week; sixty-five per cent. earned less than $8 a week.

The New York Factory Investigating Commission reports that of nearly 3,000 saleswomen studied throughout the State, one half (fifty-one per cent.) earned less than $7, and sixty-one per cent. earned less than $8. In New York city, where living expenses are highest, forty-four per cent. earned less than $7.

The department store is the only great business in which great capital is invested which admittedly seeks to employ chiefly girls who are living at home. The average pay shown in these reports is so low that it is acknowledged that girls cannot support themselves by what they earn.

Yet someone must pay the difference between the earnings of the girls and the expenses of living. Is it not a fair charge upon the great industry which employs them, rather than upon the girls and women themselves, a large proportion of whom, as we have seen, are helping to support or alone are supporting themselves or their families? For women who are dependent on their earnings the difference between income and unavoidable expenses is made up in one of three ways, says the New York commission.

They may live in subsidized boarding houses or homes for working girls, where charity pays a part of their maintenance, or, secondly, they may live with such excessive economy and upon such short rations that health is shattered and future earning capacity is permanently undermined. Thus the worker herself is made to pay unfairly in strength and vitality, instead of receiving a living wage from the industry that employs her; and, lastly, in some cases the impossibility of living upon the pittance which they are paid leads undoubtedly some women to supplement these earnings by leading an immoral life.

The question naturally arises as to what can be done to help in this situation. The Consumers League, which now has branches in twenty-two States, has long urged the shopping public to feel and to exert its responsibility as the indirect employers of these girls and women. Just as merchants provide all the commodities which their customers desire, in endless variety, so it is reasonable to suppose that they will provide conditions of employment which their customers approve if the desire is strongly enough expressed. But in this matter the individual customer or consumer can do little alone and singlehanded. Only large groups or associations of shoppers can effectively protect against conditions of employment which they do not approve for the girls and women who serve them in the stores, or whose labor supplies their needs and luxuries. The public too, is ultimately responsible for the enactment of the laws which are the most just and the most effective means of securing adequate protection for the workers. Such laws are enacted and enforced only when the public demand is sufficiently strong. In New York State the labor department has this year been entirely reorganized, and its powers widely extended by the legislature. It needs now the intelligent support of the community in its new efforts to safeguard the lives and health of the millions of wage earners of the State.
A SUGGESTED IMPROVEMENT IN THE ALLIS ETHER INHALER.

BY NELSON DU VAL BRECHT, M. D.,
Washington, D. C.

The form of Allis's ether inhaler that I have seen in universal employment has no handle. It must be held by the stretched left hand, often for hours at a time. The smooth metal sides of the inhaler become slippery in a short while from the grease which is put on a patient's face preparatory to administering ether, and this adds to the difficulty of holding the apparatus. As a rule patients struggle when going under ether, and the inhaler is apt to slip from the anesthetist's grasp. His fingers and hand become cramped and tired during protracted anesthesia. The right hand of the anesthetist is always engaged either in dropping the ether on to the top of the inhaler or in holding the patient's jaw forward. All of these difficulties and inconveniences can be obviated by having a handle attached to one side of the inhaler. This handle can be so constructed as to permit of its attachment to either the right or left side of the inhaler, so that the anesthetist can change hands; or it will be useful for ambidextrous individuals. The handles being detachable, the inhaler need occupy no more space in an instrument rack than the old style.

---

Therapeutic Notes.

Treatment of Pulmonary Emphysema.—S. I. de Jong, in Journal de médecine de Paris for April 12, 1913, states that where emphysema is accompanied by asthma and chronic bronchitis, the treatment of the asthmatic paroxysms should be the same as in ordinary cases of this affection, viz., injections of morphone, inhalation, ethylidione, or of fumes or powders containing stramonium. Inhalation of the following solution, sprayed into the nose, is often of advantage.

R Atropina sulphata, ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... EMETINE IN AMEBIC DYSENTERY.

The curative value of ipecacuanha in amebic dysentery has long been recognized, but while some observers have obtained uniformly favorable results, many have reported a relatively large number of failures. On the whole, valuable as the remedy has proved to be, it has failed, even where the identification of cases as amebic dysentery was beyond question, to merit the rank of a specific. Emetine hydrochloride, an alkaloid of ipecac introduced by Leonard Rogers last year, seems, however, to be increasingly proving its rights to this distinction.

Vedder had previously shown that emetine, in high dilution, possessed the power of destroying amebae in broth cultures; Rogers confirmed this observation by testing the effect of emetine hydrochloride on Entamoeba histolytica in dysenteric stools. When mucus containing numerous active amebae was placed in a solution of the alkaloid, the pathogenic organism was immediately killed; a solution of one in 100,000 sufficed for this purpose, while a solution of one in 10,000 produced disintegration of the amebae, or at least material alteration of their microscopical appearances. Clinically, emetine proved greatly superior to ipecac; it did not cause vomiting in patients in whom ipecac had, as it often does, provoked this symptom. Being administered subcutaneously, it is rapidly absorbed and proves promptly effective. Moreover, it presents the great advantage of affording a reliable agent, thus eliminating a drawback which has often compromised the results obtained with ipecacuanha, viz., marked differences in the activity of its preparations. Emetine hydrochloride being uniform as to its physiological action, its administration can be gauged accurately.

Besides proving curative in amebic dysentery, emetine hydrochloride, administered subcutaneously, will arrest the secondary hepatitis and prevent hepatic abscess. If the latter has already developed, evacuation by means of a trocar and injections of emetine into the pyogenic cavity will arrest the morbid process, especially if the remedy is administered subcutaneously at the same time. Chaufard recently reported a case in which the patient evacuated daily one half pint of pus from a hepatic abscess, through a bronchohepatic fistula. Suppuration ceased in six days, the temperature falling to normal, and complete recovery followed promptly. This is but one example of many now available in literature. The subcutaneous dose is from one third to two thirds of a grain, even the latter dose having failed to produce the least untoward effect.

It is generally believed that amebic dysentery is solely a tropical disease; but this is due to the fact that examination of the stools is neglected in a large proportion of the cases met with in temperate countries. It is common in the United States, especially at low altitudes near the sea level. Up to 1908 Johns Hopkins Hospital, a comparatively new institution, had received 182 cases of dysentery, practically all of which proved to be of the amebic type.

THE CURE OF MOUTH BREATHING.

The procedure now usually followed in establishing nasal respiration in cases of mouth breathing consists in carrying out operative measures, whenever these are indicated, prescribing breathing exercises, and requiring the patient voluntarily to respire through the normal channels. In some instances, as is well known, mouth breathing persists notwithstanding these measures, especially at night, when volition is in abeyance. Unsatisfactory trial of strapping or bandaging at night in these cases has led W. W. James (Proceedings of the Royal Society of Medicine, May, 1913) to devise an apparatus consisting of a wire frame of German silver, gilded after completion, over which thin sheet rubber is stretched. The apparatus is placed at night inside the lips and cheeks, resting upon the outer surfaces of the teeth and gums, and renders mouth breathing quite impossible. An accurate model of the jaws, extending as far back as the first molars on either
side, is essential if the wire frame is to be a success. The frame consists of two horizontal wires—the upper dipping down in the midline to form a depression corresponding with the frenum labii, and five vertical wires, all evenly soldered together. Rubbing of the mucous membranes is avoided by making the frame large enough to be steady and by avoiding bony eminences. A supply of rubber is given to the patient, with directions to change it frequently.

Such conditions as gingivitis and pyorrhea alveolaris are markedly improved, according to James, by the use of this apparatus. Chronic sore throat and nasal catarrh are also sometimes greatly benefited. The apparatus should be worn until normal respiration is quite established, when it may be left off on alternate nights and later completely.

SMOKE AND HEALTH.

The Monthly Bulletin of the Department of Health of the City of New York for the month of April, 1913, gives an interesting résumé of the nuisance of smoke, cinders, and gases, and the efforts made for its suppression. The limitations of the Board of Health in combating the smoke nuisance from vessels in the harbor, from federal reservations, and from railroads and large corporations are dwelt upon, and it is pointed out that certain of these offenders are not under the jurisdiction of the board, while in other cases conviction before a magistrate is most difficult, and even after conviction the fines imposable under the law are not deterrent, for, the worst offenders are large corporations and power plants, public utilities, etc.

In the development of industrial efficiency there has been a tremendous centralization of the power producing elements. It has come about likewise that in the great power plants are centralized also the smoke nuisances which formerly were distributed more evenly over the city. Cinders, smoke, and noxious gases seem to be an all too frequent accompaniment of industrial development and centralization. It may well be asked, however, why proper methods of smoke and gas consumption cannot be instituted in these large plants. Of course, to stop the operation of such a plant, even for a short period of time, or to "vacate the premises" for an offense against the smoke ordinance, would be absurdly ill considered, and would react directly on industrial efficiency, public comfort, and general safety. This is particularly true in the case of an electric power plant such as the Waterside Station of the New York Edison Company at Thirty-eighth Street and the East River, which, as the Bulletin says, "is eminent both as a public utility and as a persistent violator of the ordinance against smoke and cinders." To stop the operation of this plant would be to darken the streets, put most of the elevators out of commission, and suspend the operation of some traction lines and numerous factories, as well as to seriously impair the high pressure fire system. This company has been repeatedly warned, summoned, convicted, and fined, according to the Bulletin, and the nuisance goes on unabated.

Not alone does the discomfort and esthetic offense caused by this nuisance demand its effective abatement, but of increasing importance is the economic waste and inefficiency involved in dense clouds of factory smoke, to say nothing of the deleterious influence on the public health. Contrary to general belief, the ordinance does not prohibit the use of soft coal, confining itself to attacking the nuisance as such, no matter what the source, and prohibiting the discharge of "dense smoke." The present section of the Sanitary Code reads as follows:

Section 181. No person shall cause, suffer, or allow dense smoke to be discharged from any building, vessel, stationary or locomotive engine, or motor vehicle, place or premises within the City of New York or upon the waters adjacent thereto, within the jurisdiction of said city. All persons participating in any violation of this provision, either as proprietors, owners, tenants, managers, superintendents, captains, engineers, firemen or motor vehicle operators, or otherwise, shall be severally liable therefor.

The Bulletin goes on to say that it is necessary to have an accurate definition of the term "dense smoke." The courts have construed the term "dense smoke," as used in the ordinance prohibiting its emission, in the sense in which it is generally understood, and the courts have also stated that they "will not indulge in any subtle distinction as to what is meant thereby, but will construe it as ordinarily understood by people in general."

The smoke nuisance is no small problem in modern city life, and whether it falls more properly within the province of the police or as at present of the Board of Health, the best interests of this city and of every city demands its abatement.

SMALLPOX AND VACCINATION.

In the course of his study of 1,163 cases of smallpox observed by him in the city, and port of Liverpool, Dr. William Hanna, assistant medical officer of health, noted that among 943 cases of smallpox vaccinated in infancy, there had been twenty-eight deaths, or 2.9 per cent., while among 220 unvaccinated, there had been sixty deaths, or 27.2 per cent.; the ratio of deaths to attacks being thus ten times as great in the unvaccinated as in the vaccinated. These figures are, in a general way, confirmatory of the common experience of smallpox hospitals as to the life saving influence of vaccin-
ation. The opponents of vaccination, in order to discredit the statistics of smallpox hospitals, are forced to charge, as they virtually do, a world wide and century long conspiracy among the officers of these institutions to falsify the classification of the vaccinated and unvaccinated groups. The charge is that, being in favor of vaccination, the physicians are so biased that their observations are worthless. If the observations of men of vast experience in smallpox are worthless, what can be said of the observations of the paper statisticians opposed to vaccination?

Doctor Hanna makes an interesting contribution to the study of the mutual influence of concurrent vaccinia and smallpox in cases in which vaccination was performed during the period of various incubation. In consonance with the views of others, he finds that a vaccination performed subsequent to infection with smallpox, will "take" and pass through its typical course, up to the date of onset of symptoms of smallpox. The chances of suppression or favorable modification of the oncoming smallpox are in inverse ratio to the period elapsing between smallpox infection and vaccination; the later the smallpox appears after vaccination the greater is the opportunity for the vaccination to be successful and develop its countering immunity. He states that "vaccination requires nine days to develop an immunity which will absolutely prevent or minimize an attack of smallpox."

Some interesting observations on the question of vaccination after the onset of smallpox are also recorded. "The operations performed subsequent to the appearance of symptoms were unsuccessful." Doctor Hanna believes, however, that in some cases the vaccine organisms introduced into the system may have had some modifying effect, although the reaction was not typical.

In patients vaccinated late in the course of the disease, no reaction appeared at the site, except, of course, the usual scarification crust. An erroneous judgment may thus be reached through attributing the increased variolous eruption about the vaccination site to the effect of vaccination.

TONSIL OPERATIONS.

We are evidently drawing near to the end of what seems to have been a veritable removal of tonsil epidemic. Judging from the trend of present opinion and thought on the subject, the wholesale destruction of the tonsil will soon be a matter of the past. Recently the section in laryngology of the New York Academy of Medicine was asked by the Associated Outpatient Clinics of the City of New York to advise them whether the widespread practice of tonsil extirpation should be continued; whether the medical school inspectors should urge upon the parents of the children the desirability of tonsil operations, and whether such operations should be performed in dispensaries.

The school doctors and nurses have been conducting what virtually amounted to a crusade against the tonsil. They recommended that tonsils be cut out when there was the slightest excuse for it, and, as a result, many ignorant parents insisted that this be done even when the advice of the laryngologist consulted was to the contrary. The dispensaries are swamped with cases of hypertrophied tonsils. The work is often done in a slipshod fashion, very frequently without anesthesia, and in places where no recovery rooms are available. Numbers of cases are known to have been followed by serious hemorrhages, some ending fatally.

The report of the section in laryngology in answer to the above stated questions is significant and instructive. In the first place, the great majority of the members of the section favor tonsillectomy, as against tonsillotomy. Secondly, they have come out strongly against the ill advised insistence on tonsil removal on the part of the school inspectors; and, thirdly, they have taken an unmistakable attitude against the performance of either tonsillectomy or tonsillotomy in dispensaries. Both of these operations are considered major operations which should have the facilities of a hospital.

THE LIFE CYCLE OF THE BITING FLY.

In a preliminary account published in the Philippine Journal of Science for February, 1913, Dr. M. Bruin Mitzmain duplicates the information prescribed by Newstead in the Journal of Economic Biology. We thus read that the age at which Stomoxys calcitrans begins egg laying has been determined in bred flies to be nine days. The maximum number of eggs produced by a single stomoxys may be stated as at least 632 and possibly 820. As many as twenty depositions may be made in the lifetime of a female. The incubation period for these eggs is from twenty to twenty-six hours at a temperature of from 30° to 31° C. The larval stage under best conditions is usually from seven to eight days. The imago emerges from the puparium generally in five days. The fly of either sex takes its initial bite in from six to eight hours after emergence. Flies of this species have fed experimentally on seventeen species of vertebrates including mammals, reptiles, and birds. In feeding on live stock, Stomoxys calcitrans makes a wound with its labium, from which nonbiting flies suck blood. The female may live at least seventy-two days and the male ninety-four days. The development of Stomoxys calcitrans varies considerably, depending upon the environment, under the most favorable conditions.
OBITUARY.—

HORACE JAYNE, M.D., of Philadelphia.

Dr. Horace Jayne died suddenly at his home in Wallingford, Delaware County, Pennsylvania, on Tuesday, July 8th. Born on March 5, 1859, he received his education at the University of Pennsylvania, taking the degree of A. B. in 1879 and graduating as M. D. in 1882. In 1882 and 1883 he studied biology at the universities of Leipzig and Jenia, where he attended the lectures of Ernst Haeckel, and in 1883 and 1884 at Johns Hopkins. At this time he became assistant instructor of biology in the University of Pennsylvania, and soon afterward was appointed professor of vertebrate anatomy and secretary of the faculty of biology; while from 1889 to 1894 he served as dean of the college faculty. In 1895 he became director of the Wistar Institute, which office he retained for several years: when he resigned to become a member of the board of trustees of the Drexel Institute.

Doctor Jayne belonged to a family whose members have been noted not only for their scientific attainments but also for their philanthropy. He was a fellow of the College of Physicians of Philadelphia and of many scientific societies. He was a prolific writer and has contributed many valuable essays to the literature of biology.

News Items.

Smallpox on an Ocean Liner.—A case of smallpox was discovered in a steerage passenger of the North German Lloyd liner Koln as it neared Philadelphia, on July 10th, and as a result the steamer was held at Government Quarantine Station at Marcus Hook until about fourteen hundred passengers were vaccinated and the vessel fumigated.

Philadelphia Civil Service Commission.—Among the positions for which this commission will hold examinations in the near future are the following in the medical service: July 30th, chief nurse and nurse, Department of Public Health and Charities; July 30th, chief nurse and nurse, salary $75 to $125 a month; assistant physician, resident, $600 to $900 a year, with room and board; assistant physician, resident, $600 to $1,000 a year, with room and board.

New Hospital for the Bronx.—The Bronx Hospital Association, which for the last year and a half has maintained a well equipped dispensary at 1385 Fulton Avenue, has purchased a site on Crotona Park East and Charlotte Street, on which will be erected an eight-story hospital building, at an estimated cost of $300,000. The directors of this hospital include Dr. Abraham Jacobi, Dr. Willy Meyer, Dr. Wolff Freudenthal, Dr. Samuel W. Lambert, Dr. H. H. M. Lyle, and Dr. George W. Jacoby. The new institution will be nonsectarian and will be called the Bronx Hospital.

A Commission for the Study of Ventilation Problems.—Professor C. E. A. Winslow, of the Department of Public Health of the American Museum of Natural History, has been appointed chairman of a commission to carry on an experimental study of problems of ventilation. The other members of the commission are: Dr. Frederic S. Lee, professor of physiology, Columbia University; Professor E. L. Thormeke, of Teacher's College, Columbia University; Professor E. B. Phelps, of the Massachusetts Institute of Technology; Dr. James Alexander Miller, of New York, and Mr. D. D. Kimball. An appropriation of $50,000, to be expended during the next four years, has been placed at the disposal of the commission, this fund being a part of the gift made by Mrs. Elizabeth Milbank Anderson to the Association for Improving the Condition of the Poor.

The Rockefeller Institute for Medical Research for Medical Research for Treatment. It is planned to admit such patients again during the coming summer, and after July 15th all such patients applying for admission will be cared for in the hospital. Judging from the reports of the Department of Health, it is not likely to be as large as it was during the past two years, though a considerable number of cases are occurring and applications for admission have already been received at the hospital. Many physicians will be very glad to know of the hospital where they may send such patients, and if they will telephone to the hospital, an ambulance will be sent promptly for the patients.

An Exposition of Safety and Sanitation.—The first international exposition of safety and sanitation ever held in America will take place in New York in December of this year, under the auspices of the American Museum of Safety, of which Dr. William H. Tolman is the director. Every branch of American industrial life will be represented at the exposition. The exhibits devoted to safety, health, sanitation, accident prevention, welfare, and the advancement of the science of industry. By a special act of Congress, exhibits from foreign countries are admitted to the exposition, and there are twenty-one museums of safety in Europe, and all these museums will contribute to the exposition. In the United States every year 40,000 workers are killed, and 2,000,000 are injured, while 3,000,000 become ill from preventable causes. The main object of the exhibition is to point the way to the conservation of human resources.

Martyrs to the X Ray.—Dr. Charles L. Leonard, of Philadelphia, chief of the Polyclinic Hospital staff, and an expert in electrotherapeutics, is said to be in a serious condition from the effects of the x rays, to which he has been working for many years. Growth starting in one hand made it necessary some time ago to remove the hand, and recently the whole arm was removed. Every effort is being made to check the further spread of the malady. Dr. Leonard assisted Dr. William L. Clarke, also of Philadelphia, in treating Mr. Burton E. Baker, inventor and manufacturer of x ray apparatus, who died in Hartford, Conn., on July 10th. Mr. Baker began his work with the rays in 1885, and it was in 1905 that the first signs of disease were noticed. He continued his work, however, and six months ago it was found that his whole system had been affected by the cancerous growth. Radium and surgery were tried, but without stopping the disease. It is said that the doctors who have treated Dr. Leonards and the men have lost their lives through the continued use of the x ray, about twenty being physicians. These men, however, all used the rays in the earlier years of their discovery and before the danger attached to their use was understood. In these days great care is observed, the experimenters being protected by thick lead screens.

Gifts and Bequests to Charities.—The Mayor of Hoboken, N. J., has received from the Hamburg-American Steamship Company the sum of $5,000, as that city's share of the proceeds of the public inspection of the Imperator. Of this sum St. Mary's Hospital will receive $2,500, Christ's Hospital, $1,000, and the North Hudson Hospital, $50.

Charitable bequests, aggregating $65,000, are contained in the will of Mrs. A. W. Cooper, of New York, and recently in Philadelphia. Among these bequests is one of $50,000 to the Presbyterian Hospital.

Notice has been filed of the contest of the will of the late Henry E. Rutherford, who left $300,000 to the Rockefeller Institute for Medical Research.

Mr. Arthur James has given to the Middlesex Hospital, London, the income from £20,000, as a memorial to his brother. The money is to be used to carry on cancer research work.

The will of Mrs. Elizabeth M. Newton, of Fredonia, N. Y., who died a few days ago in California, contains a bequest of $150,000 to establish a tuberculosis hospital in Chautauqua County.

The Pennsylvania Hospital will receive $5,000, under the terms of the will of Charles M. Morton, who died in Atlantic City on May 18th.
Personal.—Dr. John R. McDill, of Milwaukee, Wis., has been appointed associate professor of surgery at the University of Chicago.

Dr. Emil Abderhalden, professor of physiology in the University of Berlin, has declined the call to Vienna as the successor of Professor Ludwig.

Dr. Robert L. Bartlett, of New York, has been appointed superintendent of the Oneida County Hospital at River Falls.

Dr. Henry Wireman Cook, of Minneapolis, was elected president of the American Association of Medical Examiners, at the annual meeting of the association, held recently in Minneapolis. Doctor Cook succeeds Dr. Frank W. Foxworthy, of Indianapolis, who becomes first vice-president.

Medical Board of Kingston Avenue Hospital, Brooklyn.—Announcement is made by the Department of Health of the City of New York of the appointment of six members of the staff to consult with the members of the medical board of this hospital, which is a city institution for the care of infectious diseases. These physicians are as follows: Consulting physicians, Dr. John A. McCorkle, Dr. Jacob Fuhs, Dr. G lentworth R. Butler, and Dr. Elias H. Bartley; consulting surgeon, Dr. H. Beekman Delaoutre; consulting osto1ogist, Dr. Henry A. Alderton; consulting dermatologist, Dr. James McFarland Winfield; attending physicians, Dr. Frank M. Sharpe, Dr. Raymond Clark, and Dr. C. H. Webster; consulting surgeons, Dr. John F. Waterman; attending surgeons, Dr. Warren Duffield, Dr. John A. Lee, Dr. Walter A. Sherwood; obstetrician, Dr. O. Paul Humphstone.

Maine Medical Association.—The sixty-first annual meeting of the association was held in Portland on Wednesday and Thursday, July 24 and 25, under the presidency of Dr. R. H. Marsh, of Guilford. The following officers were elected for the ensuing year: President, Dr. W. C. Peters, of Bangor; vice-presidents, Dr. Eben Marston, of Bangor, and Dr. Ed. E. Ford; secretary, Dr. John B. Thompson, of Bangor; treasurer, Dr. E. W. Gehring, of Portland; councillors, Dr. Stephen Webber, of Calais, and Dr. T. S. Dickson, of Houlton. The following committees were chosen: Scientific work, Dr. F. Y. Gilboy, of Bangor; Dr. W. P. Plympton, of Portland, and the secretarv ex-officio; policy and legislation, Dr. D. A. Robinson, of Bangor, Dr. T. E. Hardy, of Waterville, and Dr. S. T. Beacher, of Augusta; necrology, Dr. James A. Spalding, of Portland. The next convention will be held in Portland early in June, 1914, but the dates were not fixed.

Resolution of the Board of Health Regarding the Use of the Friedmann Test.—On May 29, 1913, the board of health of New York, with the approval of its medical advisory board, adopted a resolution providing for the official supervision of immunization with living bacteria, the result of which was the closing of the recently established Friedmann Institute. The resolution in part to the effect that the board of health is empowered to prescribe regulations for the use of the Friedmann test, as under the new rule. On June 17th the board adopted a resolution which forbade the use of the treatment, except in those cases where the patients had already been treated at various hospitals and at the Friedmann Institute, and prescribed very minutely the conditions under which rejections might be made. The resolution reads as follows:

1. The injection or treatment of human beings within the city of New York with the F. F. Friedmann test (which contains living bacterial organisms) is prohibited, except under the following regulations and restrictions:

2. No person may be treated, according to the foregoing, who did not receive one or more such treatments with the same kind of living bacterial organisms, in New York city, previous to May 30, 1913.

3. These treatments may be administered only in the following named hospitals: Bellevue Hospital, Mt. Sinai Hospital, Metropolitan Home and Seton Hospital, and any other that the Board of Health may approve when arrangements have been made for proper observation of the case.

4. Only those persons may be so treated who reside in one of the aforesaid hospitals or who are attending patients of one of such hospitals in which they receive said treatment as often and at such times as such physicians in charge of said hospital deem it advisable for their own observation.

5. No person may receive treatment according to the foregoing unless he has presented to his physician a duplicate, by a physician who is duly authorized to practise medicine in New York, of the certificate of the findings of the patient, in the treatment.

6. No person may be so treated until he or his parent or guardian, in case of a minor, has signed a declaration, in duplicate, stating that he desires these treatments continued.

CORRESPONDENZ-BLATT FÜR SCHWEIZER AERzte

The Operative Treatment of Floating Kidney.—Theodor Kocher thought that this operation was "something new under the sun," but finds that it has been performed by others, so far as its essentials are concerned. The kidney is laid bare by an oblique lumbar incision and brought into the wound by pressure on the abdomen, so that its lower pole can be fixed with the fingers. A strip of the fascia lata, from eighteen to twenty cm. long, by about ten cm. broad, is taken from the thigh, and its four corners secured with artery forceps. An incision about four cm. long is made longitudinally in its middle, into which the lower pole of the kidney is introduced, so that the kidney lies in the strip of fascia like a stone in a sling, and is secured in place by sutures passing through the margins of the opening and the capsule. This suture is then fastened in its desired position by sutures. By this means the lower pole can be drawn a little forward, if the upper pole shows a tendency to droop. The advantage of this method is that the kidney is kept in place without depending on any sutures in the kidney itself. He does not think it wise to draw the fascia so far over the kidney as is done by Hensch, for fear that the vessels or the ureter might be compromised, and he thinks the method will prove to be better than the "basket handle" method suggested by Werellius, of Chicago.

Tumors in the Male Breast.—Fritz Miescher observed a fibroadenoma of the mamma, in a man sixty-seven years old, which grew slowly, and a tumor of the mamma in a man fifty-two years old, of which he gives quite a detailed description; it seemed to be undergoing a cancerous degeneration, but there has been no recurrence or metastasis in three years. The author has been able to find in literature only two other cases of nonmalignant tumors in the breasts of men.

A Typical Case of Traumatic Neurosis Persisting during a Long Suit for Indemnity.—Naegeli reports a case in which fourteen examinations were made by various medical men in the course of eighteen years. He seems to think that the neurosis had been kept active by this means, and that this way of determining the insurance is posteroerous.

Epidemiological Considerations Concerning Diphtheria.—R. Klinger studies diphtheria from the point of view of prophylaxis, and concludes that in order to make an efficient fight against diphtheria it is very advisable that the bacteriological examination be made extremely extensive, so as to be practised not only in typical cases, but also in those that are scarcely suspicions—sore throats and coryzas. As soon as a case of diphtheria is established bacteriologically, investigation should be made of the surroundings of the patient, in the home, school, or institution. Bacteriological examinations are to be made until there has been a bacteriological cure.
Diphtheria bacilli remain perfectly virulent on the average for from two to four weeks from the beginning of the disease in the throat, and sometimes in the nose of the convalescent. Patients with virulent diphtheria bacilli should be isolated as long as the bacteriological condition is positive. The brothers and sisters of the patient, as well as any other children living in the same house, should be excluded from school, and not allowed to play with other children either in the house or on the street. At the same time these children should be given as much outdoor air and light as possible. The parents should be instructed by the physician how to avoid spreading the disease. The fight against diphtheria cannot be successful without the efficient cooperation of the family physician.

**MEDIZINISCHE KLINIK.**

**June 1, 1913.**

**Pain as a Symptom of Internal Disease.**—O. Roth states that the exact examination of pain is of great value because it compels us also to take into account its origin of psychic origin. Therapeutic results are greatly influenced by these. Fleiner says that the psyche plays an important part, not only in the person's becoming ill, but also in his becoming well. It is generally emphasized by all that the treatment of disease should not be dogmatic; but should always take into consideration the individualism of the patient. This demand can therefore be best satisfied when the psychic condition of the patient is not neglected.

**The Influence of Daily Atmospheric Pressure on Blood Pressure.**—R. Stehelin asserts that, aside from irregular pressure waves on separate days, we may expect to find an atmospheric influence on all patients examined. Only on certain days, however, are noticeable effects seen in the majority. If the patients in a hospital were all confined in the same rooms, we might not be justified in concluding on the effect of atmospheric conditions on particular days; but since the patients examined were in different wards, the fact that on those days all showed a striking effect in the same direction could be mainly attributed to an influence originating in the weather. The observations must be conducted with great care, so as to exclude physical or other disturbances, and patients should be selected whose blood pressure is not influenced by their own disease. Only one group of cases—patients suffering from tuberculosis of the lungs, in whom the disease showed a stationary character—was selected for examination. Of course, one must not imagine that the atmosphere acts on blood pressure in a mechanical manner. We may take it that in rarefied atmospheric conditions certain radioactive gases emanate from the earth, and thus influence blood pressure, and that lowered atmospheric pressure exerts an influence in lowering blood pressure, a fact which, in spite of limited knowledge, the author regards as being of great importance.

**Occult Glycosuria.**—L. Boros explains how the secretion of grape sugar in the urine is frequently a symptom of various ailments besides diabetes, as disorders of the liver, heart, lungs, and brain, as well as acute infections, syphilis, and also some cases of poisoning; in all of which this fact has been shown. Again, an excessive carbohydrate diet may lead to an alimentary form of glycosuria. The diagnosis of glycosuria is confirmed by the regular methods of testing for sugar. That sugar may at times be excreted in small quantities without one's being able to demonstrate glycosuria, has led the author to make special urinalyses. These disclosed in the sediment, along with yeast cells, certain materials presenting some debatable characteristics. These suggested diabetes, although all tests tried disclosed no sugar. Yeast cells, frequently present in diabetic urine, are everywhere present in the atmosphere; as soon as they settle in the urine they find many ingredients vital for their existence, especially ferment producing sugar. Oxaluric lime crystals were found considerably increased. He wishes to lay stress upon the vicarious compensatory excretions between sugar and oxaluric acid. When urine is not examined often or thoroughly, the presence of sugar may be overlooked by reason of the action of yeast cells on the spores of sugar. This fact of the action of yeast cells contains enough diagnostic and prognostic value to deserve the attention of the practitioner.

**Dietetic Treatment of Certain Forms of Chronic Diarrhea.**—C. Wegele calls attention to the treatment of diarrhea with milk diet, stating that with from three to seven litres of milk daily no improvement may result in severe forms. It occurred to him that in such patients raw fruits often brought about better results than milk alone. It was van der Scheel who conceived the idea of a combination of lukewarm milk with strawberries pressed through a sieve—one part of juice to three of milk. With this the author brought about remarkably good results. Besides the mixture he allowed only crackers and two eggs daily. Later, milk broth, whole strawberries, and from three to four eggs daily were permitted. About three pounds of strawberries were used in the twenty-four hours. In a few days the patient's general condition suddenly changed for the better. The stools became formed, their permeating odor decreased, and, above all, the prostration and stupor, which gave the picture of autoinfection, became less from day to day. It has not yet been shown how the strawberries cured, though they are said to possess a certain enzyme which greatly promoted digestion. Boiling or sterilizing the fruit deprives it of its healing power. Bananas, peaches, mellow pears, melons, and cucumbers may be used, but are not as efficacious as strawberries, especially in the early part of the treatment. Gradually the patient was allowed puree of light vegetables, etc.

**June 8, 1913.**

**Natural Immunity Dependent on Nourishment.**—Szerny explains that full term, breast fed infants present the highest rate of immunity. He finds that only a small proportion of infants die solely from methods of nourishment. The death of most of those making up the high infant mortality is due to infections. He has up to now dealt only with the nourishment most important to the infant: albumins, carbohydrates, fat, water, and salt. In connection with these important constituents of the diet, nourishment still seems to depend on those food values which are requisite only in
small quantities, but which in the greatest measure govern the vitality of the organism in greatest measure. That which maltose preparations supply to the child of the first year is later replaced by meat. With relative small quantities of this nourishment results not to be explained are attained. In this way children are protected against infection in a manner which could not be accomplished by other methods. From observations on the study of children valuable lessons may be deduced for adults.

New Discoveries Regarding the Diet of Diabetes Melitus.—B. Tausz says that Abderhalden’s researches have proved that albumin, fat, and carbohydrates develop protective ferments. Abderhalden and, independently of him, Weinland have shown that when cane sugar is added to the serum of a dog the cane sugar remains unchanged; but if the animal first be given ten c. c. of a five per cent. cane sugar solution intravenously, and then cane sugar solution added to its serum when drawn, a splitting up of the disaccharides follows at once, and this process of splitting is not temporary but continues for about three weeks. As a result of this, it is found possible for the organism to produce protective ferments against the prevalent action of carbohydrates. In diabetes the system is overstocked with carbohydrates, and were it possible to make the protective ferments active, or perhaps increase them, the carbohydrates might be oxidized to a greater extent. The carrying out of this idea is now in progress.

Experience with Codeonial.—Lena contributes the following: Codeonial is a compound of 11.76 per cent. codeonum diethylharbituricum and 82.24 per cent. of sodium diethylharbituricum. It comes in tablet form, each containing 0.17 grammes of codeonial. It was used for patients suffering with psychoses of light and severe grades, neurosis, and organic nervous diseases, in all of which neuroanesthetic difficulties and pain were present. The doses consisted of two, three, or four tablets after the evening meal. The author found that in psychosis and neurypsychosis combined with general unrest and in the severely excited the remedy does not suffice as a sedative. On the other hand, it is very useful as a soporific in patients with general nervous excitement or exhaustion of a milder nature, as well as in organic nerve affections which are combined with pain. In these it is a valuable substitute for veronal. The absence of any bad aftereffect, even following large doses, permits of its recommendation for many patients.

The Appearance and Significance of Over-tension of the Arteries.—John has made the following observations: While there are generally, though by no means always, changes in the smallest vessels of the kidneys, the vessels of the same calibre in other organs are not necessarily changed. Macroscopically the kidneys not infrequently appear perfectly normal and microscopically show only isolated connective tissue shreds, or even when they appear as typical red granular kidneys, they also show no marked abnormality clinically, with regard to function. The patients are usually short breathed (sometimes only after exertion), suffer from headache, dizziness, restlessness, a feeling of fear, and excitement. Impaired ability and uncertainty in the use of the extremities and rheumatic difficulties develop. The blood pressure may be as high as 200 mm. Hg., and there is generally a moderately hypertrophied heart. As to the heart sounds, besides the almost constant accentuation of the second sound, there is later a presystolic, galloping rhythm. In the urine are found traces of albumin, and cylinders will be discovered when searched for in the sediment. In plainly marked incompetence there is edema, with from three to twelve per cent. of albumin in the urine. In isolated cases the ophthalmoscope shows small atrophied spots in the retina.

June 22, 1913.

Treatment of Acute Lowering of Blood Pressure with Hypophysin Extract.—Klotz says that by intravenous pituitrin injections the toxic fall of blood pressure is controlled to a moderate degree and that this action lasts for some time. The good effects are generally enhanced by the addition of normal salt solution. The injection should be made at the very beginning of the fall in blood pressure and may be repeated at any time after the effect has worn off, though it should not be delayed more than twelve hours. One need not fear any cumulative effect. Stimulants, such as camphor, digalen, etc., may also be employed. Pituitrin is likewise of service in the toxemia of peritonitis, and the infection of the pneumococcus and diphtheria bacillus and pyocyanus, as well as in circulatory disturbances. Delille states that he has had good results with pituitrin in both diphtheria and pneumonia.

June 20, 1912.

Function Test of the Kidneys and Its Significance.—M. Roth calls attention to a method of testing kidney function by intramuscular injections, in various parts of the body, of coloring matter as indigo carmin and the phenolsulphonephthaleins. The first, introduced into practice by Völker and Joseph, comes in the form of a tablet containing 0.08 grammes. One tablet is to be dissolved in twenty c. c. of boiling water, and this boiled down to even a more concentrated solution. It is best injected into the lateral gluteal region. To prevent painful infiltrations, it is well to inject small quantities in various places. In five minutes, or at the latest, ten minutes, normal kidneys begin to excrete the coloring matter in the urine, which in from twenty to thirty minutes shows a deep blue. Should discoloration of the urine begin markedly later, for instance, in thirty minutes, or if after an hour it is only lightly colored, the case is undoubtedly one of defective kidney functionating. Several other coloring materials, each having some special advantage, are given by the author.

LYON MÉDICAL.

June 1, 1913.

Effects of Alcohol Injections into Nerves.—L. Bériel and A. Devic point out that the reactions caused by the introduction of "lytic" agents in nerves are not as yet well known. They report experimental work on rabbits, in which it was found, in the first place, that even with considerable pressure, only a few drops of alcohol could be made
actually to penetrate the substance of the sciatic. Degenerative changes subsequently occurred in the nerve fibres, even at a distance, but total transverse destruction of the nerve trunk never resulted, in spite of special attempts to produce it. The conclusion reached was that alcohol diffuses but little in nerve tissue, and that destructive changes take place only in fibres coming directly in contact with the alcohol.

June 8, 1913.

Vertigo in Tuberculous Patients.—C. Lesieur and L. Thévenot found, among one hundred tuberculous patients, fifty-five who experienced vertigo, sometimes sufficiently marked to cause the patients to fall. In twenty-six instances the symptom followed paroxysms of coughing; in twenty-one, various causes such as digestion and exposure to cold air, etc.; in five, meals, and in three, changes of position. The symptom occurred with equal frequency at all ages, and oftenest early in the disease. It appears to be due to abnormal sensitiveness of the pneumogastric nerve and its centres. The sequence of cough and vertigo is thought by the authors to be of considerable diagnostic value. When observed it should suggest to the clinician the possibly tuberculous nature of a bronchitis or tracheobronchial glandular disorder.

Complications in a Case of Pneumonia.—A. Lemierre and L. Coton report a case of mild pneumonia following traumatism to the chest in a diabetic, complicated on the nineteenth day by bilateral epididymoorchitis, and later by erysipelas. The blood gave a positive culture of the pneumococcus, and the authors look upon the epididymoorchitis as a metastasis of this organism, the result of the bacteriemia.

PARIS MÉDICALE

Cytology of the Fluid Contained in Cutaneous Bullae.—M. Villaret, discussing this subject in detail, states that while cytoscopic studies of the fluids obtained from cases of bullous, vesicular, or purulent dermatitis, are of but little clinical interest, they may be of diagnostic value in doubtful cases of pemphigus and erythema multiforme, in which there is an excess of polymorphonuclear leukocytes; in smallpox and herpes zoster, in which altered epithelia are found, and in plantar eruptions of the newborn, in which parasitic organisms may be detected. In Duhring’s disease there is a pronounced eosinophilia in the fluid contained in the bullae, and in pityriasis rosea the minute vesicles surrounding the diseased patches are said to enclose from the outset an excess of multinucleated cells.

June 7, 1913.

Bismuth Salts and Their Uses.—Lion has shown that when bismuth subnitrate is given to patients with excessive gastric secretory activity, either an hour before or during a meal, the drug diminishes both hyperchlorhydria and peptic formation; lowers the intensity of the digestive process in the stomach, and leads to rapid evacuation of this organ into the intestine. A high degree of total acidity still remains, but this is due in large measure to nitric acid set free from the bismuth salt. The dose advised by Lion for these cases is from ten to twelve grammes. The drug may also be given five or six hours after the meals, for the purpose of precipitating the chloride of the stomach contents and placing the organ under conditions in which there is a more marked tendency toward its evacuation. In x-ray work Lion disapproves of the use of both the subnitrate and carbonate of bismuth, owing to the danger of bismuth intoxication, and has had prepared an oxide of bismuth which is tasteless, readily emulsifiable, becomes changed to an insoluble oxychloride upon contact with the gastric juice, and is not absorbed into the blood; all risk of either nitrate or bismuth intoxication is thus avoided.

Gastrocolic Reactions.—M. Looper refers to the effects on colonic motility exerted by the introduction of food or fluid into the stomach. X-ray observations showed that the ingestion of food resulted within half an hour in well marked motor excitation of the cecum and ascending and transverse colon, but only slightly of the descending colon, and not at all of the sigmoid. Even normally, certain substances, such as coffee and alcohol, and sometimes game, lobster, fish, eggs, etc., will cause a prompt colic reaction. In stomach patients with hyperchlorhydria, dilatation, or gastropoasis, as well as in cases of enteropsisis, chronic enteritis, or mere hypere-the-sis of the abdominal visera, diarrhea, or pain, or both, may occur after meals. In enterocolitis, again, constipation due to reflex spasm of the colon, and in appendicitis, pain because of ceal spasm dragging on adhesions, may occur. The chief cause of the gastrocolic reactions is supersensitiveness, either of the stomach, colon, or abdominal nerve plexuses. Surmont and Dubus have shown that the pyloric region is the most sensitive area of the stomach in exciting colic reflexes; yet, colic contractions may begin immediately upon the entrance of food into the stomach. The secretory, vasodilator, and peristaltic hormone existing in the blood during digestion is probably a factor in the gastrocolic reaction, in addition to the purely nervous one. Prophylaxis, as regards this reaction, consists in ordering a nonirritating diet—sometimes in part predigested—slow eating, and peptic ferments. Gastric, appendicular, or ceal disorders, enteritis, etc., should be suitably treated. Sodium bicarbonate or citrate, and carbonate of calcium or bismuth, often act well. Anesthesia of the reflex may be procured by giving lime water. With some analgesic drug added, or by means of chloroform, taken fifteen minutes before each meal. Intestinal excitation may be overcome with suppositories containing 0.05 gramme of valerian, 0.05 of cocaine, and 0.02 of extract of belladonna, with or without ichthyol or tamin. Hot, moist compresses over the abdomen at night, followed by an alcohol compress for an hour in the morning, may prove useful. General tonic measures may also be indicated.

PRESSE MÉDICALE.
June 7, 1913.

Stasis Due to Altered Position of Colon.—G. Lardennois, after discussing the several possible types of colonic displacement and their causes, advises that where such displacements are marked, causing persistent obstruction, notwithstanding die,
constant care and massage, and if the kinks in the bowel are shown to be permanent by X ray examination, the patient be subjected to a Y shaped typhlo-sigmoidostomy, with resечение of the fundus of the cecum. This operation is easily performed, in particular in the cases where the cecum is distended. It is especially indicated in stenosis of the hepatic flexure. It overcomes constipation, places the colon at rest, and drains it in the best possible manner.

Adrenal Glands and Glycerina.—H. Bierry, reviewing the evidence available to the effect that the secretion of the adrenals is one of the agents regulating the amount of sugar in the blood, refers to experimental work conducted by himself with L. Morel, which proved that epinephrin can exert its action on glycogenesis through a process not involving the cerebrospinal nervous system. Epinephrin probably acts through the sympathetic system, the fibres of which are capable of activating protoplasm, as regards the elaboration of soluble ferments. The secretion of epinephrin itself, on the other hand, which at least in part contributes to keeping constant the amount of sugar in the blood, is undoubtedly dependent upon a regulatory mechanism utilizing the nervous system as its intermediary. An impulse from the medulla can be transmitted through the sympathetic to the adrenals, and alter their secretory function. The route followed by this impulse appears to be the splanchnic nerves, or, at least, fibres from the bulb, the cervical and the upper thoracic cord, which travel down with the splanchnics to the semilunar ganglia, and thence to the adrenals.

June 14, 1912.

Supertensive Medication.—Alfred Martinet, after pointing out that the production of increased blood pressure is one of the therapeutic indications most frequently to be met, expresses his preference for strychnine as the chief drug to be employed for this purpose. The initial dose should be from two to three milligrammes, and this should often be increased, according to the susceptibility of the patient. Tuberculous subjects, among others, were sometimes observed to derive the best results from the daily ingestion of from fifteen to twenty-five milligrams in three doses. The frequently employed combination of sparteine with strychnine seems a useful one. Sparteine acts rapidly, is devoid of cumulative action, and is the type of the cardiotonic drugs suitable for prolonged administration. Its isolated action on the blood pressure seems slight, but the heart effect is useful to prevent the tendency to cardiac overwork existing during the temporary pressor effect of agents, such as epinephrin, with which the author often combines it. The effective dose of sparteine is from three to six centigrammes singly and from five to fifteen centigrammes a day. Epinephrin acts only partially, that is, does not affect the majority of the deep viscera; its evanescent constrictor action is followed by dilatation, resulting, in the kidneys, in polyuria. The initial hypodermic dose should not exceed one quarter milligramme; the patient should be kept recumbent and with the head low for five or ten minutes after its administration, and should also be warned that fugacious palpitation, pallor, slight vertigo, and depression may follow. Extracts of the posterior lobe of the pituitary and their crystalline principle, hypophysin, isolated by Houssay, of Buenos Ayres, act much like epinephrin, but from thirty to sixty times more persistently. Many observers have used the extracts with favorable results in tuberculosis, and acute infections with cardiovascular weakness, as well as mitral involvements and chronic myocardiitis, with insufficiency of circulation. Hypophysin must be used in doses corresponding to 0.15 gramme of the posterior lobe, or 0.44 gramme of the whole organ; smaller doses are found effectual by the author. The four pressor drugs referred to may be variously combined or alternated in different conditions.

New Diagnostic Procedure in Pneumothorax.—V. Mandru refers to the ease and frequency with which pneumothorax is mistaken for pleurisy with effusion, and points out the desirability of having a simple test which will call the physician’s attention to the presence of pneumothorax even where such a possibility has been entirely overlooked. His procedure consists merely in the use of a syringe, such as would be employed for exploratory puncture of the pleura. When, after having effected the puncture, and the point of the needle still being in the thickness of the thoracic parietes, one draws out the piston of the syringe and then lets go of it, the piston returns to its former position, owing to the vacuum established. If, on the other hand, the point has entered a pleura containing gas, the latter penetrates into the syringe after the aspiration, and the piston, when let go, does not return to its former position. The objection which might be made to this procedure, to the effect that if the lung were punctured air from the alveoli would enter the syringe, precluding positive detection of a pneumothorax, has been found by the author to be groundless. Alveolar air enters a syringe only with difficulty. Thus, with this method one can tell with certainty whether or not there is gas in the pleura above a collection fluid.

Amino Acids and Sugars in Rectal Feeding.—A. Rendle Short and H. W. Bywaters review the more scientific contributions to the literature of this subject and cite their own carefully conducted observations on the absorption of the several food constituents from the human intestine when these are introduced in the form of enemas. Their experiments were made on the basis that the attempt to wash out the unabsorbed food matter was inaccurate. Instead of this, the authors resorted to periods of fasting, followed by periods of feeding, during both of which the urinary nitrogen and ammonia were measured. They conclude as follows: 1. The older observations on the absorption of foodstuffs from rectal enemas, based on the analysis of a rectal "washouts," are unreliable. 2. The daily output of nitrogen in the urine of patients given nutrient enemas of milk or eggs peptonized for twenty or thirty minutes demonstrates that almost no nitrogenous matter is absorbed. 3. Modern physiological opin-
ion holds that proteins are absorbed principally as amino acids. The failure of the rectum to absorb ordinary nutrient enemas is largely due to the fact that peptones are given instead of amino acids. 4. Chemically prepared amino acids, or milk pancreati-
tized for twenty-four hours, so that amino acids are separated, allows of a much better absorption of nitrogenous foodstuffs from the rectum, as demonstrated in five cases by the high nitrogen output in the urine. 5. The low output of ammonia nitrogen shows that this high output was not due to the ab-
sorption of putrefactive bodies. The rectal wash-
ings were not offensive. 6. Dextrous is much bet-
ner absorbed than lactose, and relieves the acido-
sis of starvation. 7. Fat is not well absorbed. Sarcely any of the fat of ordinary milk enemas is retained.
8. The best nutrient enema consists of milk pancre-
tized for twenty-four hours, with five per cent. pure dextrose.

Lancet.
June 28, 1913.

The Dietetic Treatment of Gout.—Archibald E. Garrod discourses at some length on the concep-
tions which exist as to the relation of food to the disease, and with regard to diet remarks, “There are certain general principles which must be conformed to if we are to do the best for our patients.” The food should be adequate in amount, the main classes of foodstuffs should all be represented, there should be preferably some restrictions of the proteins; the food should be well, but plainly, cooked, and diges-
tible. Twice cooked, rich, and highly seasoned foods should be excluded. Foods rich in purins should be forbidden, and wines and beers avoided. Lastly, the dietary should be adapted to the individ-
ual needs of each patient, taking into account any complicating factors. If these main requirements are fulfilled, the regulation of the details may be left in the hands of the individual prescriber. He expresses the doubt as to whether we achieve as much as we think we do by dieting our gouty patients. Garrod finds it “hard to find any scientific basis for the distinction so generally drawn between red and white meats. Any special claims of the lat-
ter rest, presumably, upon their reader digestibil-
ity.”

A Note on the Preparation and Use of Sub-
gallate of Bismuth Gauze.—E. A. R. Newman sets forth the following points of advantage of this form of gauze over iodiform gauze: It is stable and can be sterilized; it is odorless, nontoxic; the bis-
muth has no tendency to dust out; equal if not greater efficiency; cheapness. In addition, it has the advantage of its yellow color over other forms of bismuth gauze, which, being colorless, cannot be distinguished from nonimpregnated gauze. The gauze is prepared quite readily, after washing and cutting into the proper pieces; it is first weighed and the quantity of the bismuth is calculated; this is then emulsified in a mixture of one part of gly-
cerin and two parts of alcohol; the salt is added to the glicer, and the alcohol is introduced during constant stirring. The gauze is to be moistened in water and immersed in the emulsion, while it is being stirred. Next, the emulsion is kneaded into the gauze, which is hung up to dry. It is then

folded and put up as desired, being sterilized by heat. This method may also be used for the prepara-
tion of other antiseptic gauzes.

Two Cases of Vein Grafting for the Mainte-
nance of a Direct Arterial Circulation.—J. 
Hogarth Pringle introduced about two inches of the 
internal saphena vein into the course of the brachial 
artery in one case, and four inches of the same vein 
into the popliteal in another. In each case the vein 
was removed from the patient on which the operation 
was made, and in each the graft “took” without 
any difficulty whatever, and the circulation dis-
tally to the graft was completely restored.

A Practical Method of Growing the Acne 
Bacillus from the Comedo.—T. H. C. Benians 
drops an expressed comedo, from the sterile glass 
tube used for obtaining it, into a tube of neutral 
broth medium; on the surface of this he then floats 
sterile olive oil or lard and incubates for eight to 
ten days. At the beginning of the period of growth 
the bacilli predominated, but soon the growth is 
inhibited and the acne bacilli take the ascendancy, 
so that by the end of the required time there are 
less than ten per cent. of the former in the vaccine 
made from such cultures. The acne bacilli in these 
cultures collect in the form of a granular deposit 
at the bottom and sides of the tube. In the prepara-
tion of the vaccine this deposit is removed, washed, 
and made up with saline solution for use. He 
believes his method does not depend solely upon the 
oil for the maintenance of anaerobic conditions of 
culture, for oil is known to be somewhat permeable 
to oxygen. The probability is that the growth of 
the staphylococci at first liberates alkali, which forms 
a layer of soap under the oil, thus completing the 
aerobic barrier. The rationale of the method is the 
hastening of the growth of the acne bacilli by 
aerobic conditions of culture, while such condi-
tions accomplish the further object of killing off 
most of the staphylococci, thus preventing them from 
overcoming the acne bacilli. The great advan-
tage of the method lies in its simplicity, to which 
may be added the shortening of the time required 
for the preparation of an autogenous vaccine.

BOSTON MEDICAL AND SURGICAL JOURNAL.
July 3, 1913.

Some Abuses in Surgical Practice.—Homer 
Gage says that the most significant and important 
results of the Surgical Congress held in New York 
last fall seemed to him to be the recognition of the 
fact that major surgical operations are being ad-
vised and undertaken by men with little or no 
surgical experience, and the call for some action 
on the part of the profession to safeguard the 
science of surgery and the public from the practice 
of untrained and incompetent men. The ability to 
do major surgical operations and to get by with 
them because the patient has justly outlived the 
ability to see, he thinks, a serious menace, not only to the public, but to surgery itself, and he looks forward with great interest and hope to the efforts of the new College of 
Surgery to so standardize the requirements for 
the practice of surgery as to discredit, and as far 
as possible eliminate, the incompetent. He then 
attacks the type of radical surgeon who frequently 
performs unnecessary and even unwarrantable
operations, a practice which seems to be too common and to be increasing. "Some operations should be radical, but no surgeon should be so." The surgeon should be neither conservative nor radical, but should hold a middle course between the two extremes of overdelay and overactivity. He urges greater care in diagnosis; "hasty snapshot diagnosis have certainly led to much illadvised and unnecessary opening." It is not necessary to have a fatal result to the operation fail; in many cases the only result is the substitution of one form of complaint or disability for another, with no definite physical signs, no clearly defined pathology, but many distressing subjective symptoms. The same tendency to operative excess is shown in the different specialties: "Witness the muscles cutting operations of the oculists, the removal of tonsils and adenoids by the laryngologist, of nasal spurs by the rhinologist, and the extraordinary increase in the number of mastoid operations by the otologist—all of these, like the others, are eminently useful and necessary procedures, but the indications for their performance are easily exaggerated by the enthusiasm and zeal of an impatient attendant." Surgical intervention should be undertaken only after a most careful and thorough study of the conditions for which relief is sought, of the methods that may be employed to secure it, and by men whose training and experience qualify them to meet intelligently the dangers and complications that may be encountered. The purely mechanical side of surgery has received too large a share of our attention, but to possess a sound judgment as to the indications and counterindications for operations is far more important and valuable than the acquirement of mere mechanical skill. Much of our overinterference will seem as absurd to our successors as the overmedication of our fathers seems to us.

A Case Illustrating the Efficiency of the High Frequency Current in the Treatment of Tumors of the Bladder.—J. Dellinger Barney reports a case in which a tumor of the bladder was burned with the high frequency current on four successive weeks, and again five times at intervals of two weeks. At the last sitting the tumor consisted of a few small nodules, but for the first time a number of little papules were to be seen clustered around the parent growth on the bladder wall. The diagnosis of infiltration by a malignant growth was made, and operation performed. The entire thickness of the bladder was removed for a distance of half an inch outside the limits of the site of the tumor. Microscopical examination of this piece of tissue failed to reveal any evidence of tumor cells. Nine months later the bladder was normal, except for a somewhat puckered scar and a moderate cystitis. So far as the writer knows, this is the first case in which a bladder tumor treated and presumably cured by the high frequency current has been actually inspected at a subsequent time either at operation or post mortem.

Separation of the Epiphysis of the First Metacarpal Bone. Report of Two Additional Cases.—William Pearce Coates believes that increased care and thoroughness in the examination of injuries about the carpus in children, with good x-ray pictures, will probably show an increasing number of separation of the epiphysis of the first metacarpal bone. This injury may in children take the place of the Bennett fracture in the adult. Union with some displacement of the epiphysis does not seem to affect the usefulness of the hand to any marked degree.

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.
July 5, 1913.

Lange's Colloidal Gold Chloride Test on the Cerebrospinal Fluid in Congenital Syphilis.—C. G. Grulee and A. M. Moody have experimented upon twenty-five cases; ten of clinically congenital syphilis, seven of suspected congenital syphilis, and eight nonsyphilitic cases. They conclude that while from such a small series of cases one cannot show that the gold chloride test gives specific reactions in cases of congenital syphilis, one is justified in saying that the reaction shown in the writers' cases was very suggestive and might prove to be of much more value in the diagnosis of congenital syphilis than any laboratory reactions heretofore presented. They lay stress on the point that, in common with all laboratory tests, the gold chloride reaction must always be regarded only as an aid to clinical diagnosis, and direct that a case showing clinical signs of congenital syphilis should be confirmed by the reaction of the cerebrospinal fluid to the colloidal gold solution of Lange. Although it is possible that treatment will distinctly modify this reaction, it will be to a less degree than with the Wassermann reaction.

Exposure of the Brachial Plexus with Nerve Transplantation.—Howard K. Tuttle details the history of a case which illustrates two points: First, the mistake in closing the skin wound at the time of injury without learning the full extent of the damage, with immediate nerve suture, a neglect which is comparable with the suturing of incised wounds of the wrist and leaving the cut tendon disunited; second, the results we may obtain in seemingly hopeless cases, and the fact that even a long chance is worth taking.

The Treatment of Profuse Kidney Hemorrhage by Means of Epinephrin.—Herman L. Kretschmer reports a case of profuse painless renal hemorrhage in which rather remarkable results were obtained from injections of epinephrin made directly into the pelvis of the kidney through the ureteral catheter. The writer does not assert that epinephrin is a specific in all cases of renal hemorrhage, as many cases are due to tumor, tuberculosis, and stone. The use of this treatment is suggested, however, pending an exact diagnosis of the cause of the hemorrhage.

Purpura, Urticaria, and Angioneurotic Edema of the Hands and Feet in a Nursing Baby.—Irving M. Snow reports this case in detail, not because it is unique, but as a clear and full description of a concurrent purpura and angioneurotic arthritis edema developed in a young healthy baby. The patient was a fat infant thriving on its mother's milk. The writer observes that such symptoms might excite unnecessary alarm and false con-
PITH and, nitrogenous is as bis surgical The amination with turbid.
foods to lessen the may be classified as tubular, vascular, or azotemic, which classification is an aid in treatment. A combination of the types may exist, but one type will predominate and indicate the line of treatment. Treatment should aim to spare the incapacitated part or function. Exclude chlorides in tubular nephritis; nitrogenous foods in the azotemic variety, and restrict the fluids in the vascular form.

A Note on the Treatment of Cough in Advanced Pulmonary Tuberculosis.—J. Douglas Blackwood, Jr., had his attention called by an advanced tuberculosis patient to the fact that when he took acetylsalicylic acid (aspirin) in the evening, his cough was much relieved and his sleep less disturbed. The writer advises patients with advanced pulmonary tuberculosis to take acetylsalicylic acid in doses of five or ten grains, about 8 p. m. when they are troubled with excessive cough at night. The smaller dose is usually sufficient to control the cough, and is not so liable to cause a night sweat as is the larger dose.

MEDICAL RECORD.
July 5, 1913.

Methods of Localization of Spinal Tumors with Reference to Their Medical and Surgical Treatment.—E. Castelli concludes that the study of neuropathology shows that neurology is asserting itself as a very definite specialty, and that it is gradually creating positive methods of physical examination which will in the future render the diagnosis of the nature and localization of nervous disease far more precise than the diagnosis of other diseases. The clinician who knows how to find the projection of every square millimetre of the nervous organs on the surface of the body in the form of a motor, sensory, or reflex manifestation, will be compelled to show the relation of cause and effect and localize lesions with a mathematical precision.

In the field of neurology the conception of Charcot and the errors of his school, are fast disappearing. The real progress in the surgical treatment of nervous diseases is found to be closely connected with a more intimate union of surgeons and neurologists in the making of the diagnosis. When the nervous system is involved, the views of the neurologist must be taken into serious consideration by the surgeon. who would be well informed as to the necessity of surgical intervention, since the questions of localization and the opportunities of intervention and technic can be better weighed by the neurologist than by the surgeon. The closer association will lessen the dangers and mishaps that have heretofore marked the path of the surgery of the nervous system.

Hexamethylenamine in Surgery.—A. C. Burnham looks upon this substance as one of the best examples of a product of true chemotherapeutics, acting as a poison to the infecting organism, as quinine and salvarsan act in malaria and syphilis; that is, it injures the infecting organisms more than it does the body tissues. However administered, it appears, after a short interval, usually less than an hour, in the urine and in various other secretions, imparting in each case an antiseptic property to the secretions. Of itself, it has only a very slight antiseptic action, but when added to acid urine formaldehyde is liberated, and the urine becomes antiseptic. Experiment, however, justifies us in the assertion that this substance has an antiseptic action also in alkaline and neutral body fluids when kept at body temperatures, and that this action is greater in those cases in which stasis allows time for the liberation of formaldehyde to take place. Two important uses are attached to hexamethylenamine: first, as a prophylactic against infection; and, secondly, as a curative agent when infection is already present; the former is an important one, but it is difficult of proof and is too often overlooked. It has been most frequently used in infective conditions of the genitourinary tract, but it has been shown to be of value in septic and purulent types of meningitis and in the prevention and treatment of otitis media and mastoiditis. The dose varies with the object to be attained, from twenty to forty grains daily sufficient in bladder diseases, while in gallbladder infection, or purulent meningitis, from two hundred to three hundred grains daily may be required in grave cases. The remedy should always be given well diluted (two grains to the ounce of diluent), and is best administered by mouth, but may, if necessary, be given by rectum or subcutaneously. The three cardinal points are: Give early; give in sufficient doses; always give in sufficient dilution.

Sexual Periodicity in the Male.—C. P. Oberndorf calls our attention to the fact that certain carefully kept records on the part of normal individuals of their sexual desires and nocturnal emissions have shown significant indications, not only of a monthly, but also of an animal sexual cycle. The writer mentions the work of Kraft-Ebbing, Naecke, Moll, and Havelock Ellis, and refers to the remarks of the latter that “it is in the domain of disease that the most strenuous and on the whole the most successful efforts have been made to discover a menstrual cycle in man.” This field seems promising, because morbid exaggeration or defects of the nervous system might be expected to release from inhibition or to magnify fundamental rhythmical processes. The writer records the histories of three cases bearing on this point.

ANNALS OF SURGERY.
May, 1913.

Arthroplasty.—John B. Murphy discusses the technic and aftertreatment of sixty-two arthroplasties for bony ankylosis of joints. He makes the following comments on the prognosis of arthroplasty in general: 1. Perfectly movable, normally
functionating joints, with sliding and rotary motion of the normal type, can be and have been reproduced. 2. A new synovialoid membrane is produced, with fluid not synovial, but resembling synovial fluid, and lining cells identical with those lining the hygromata, and closely resembling the endothelial cells of normal synovial membrane. 3. These joints support full weight and traction. 4. They are painless once the process of repair is complete. 5. They are not subject to the hematomatous metastatic arthritides of normal joints. 6. A fibracartilagelike structure develops on the end of the bone, and the latitude of motion increases with time up to the full anatomical limitations in the uncomplicated cases. The production of new joints is not difficult technically, nor is it associated with great danger to life. The many details in the interposition of the flaps are essential, and must be systematically carried out to achieve the best results. Aspesis is essential, though not absolutely necessary.

Pathological Data Obtained from Ulcers Excised from the Anterior Wall of the Duodenum.—William J. Mayo says that at St. Mary’s Hospital they have excised fifty-two chronic duodenal ulcers with satisfactory results without performing gastroenterostomy. He believes that the excision of the ulcer should be accompanied by division of the pyloric sphincter, using either the Finney or the Heinecke-Mikulicz method of pyloroplasty in the closure, and that the gastroduodenal opening should be made at least two and a half inches in length. Pathological examination of these ulcers after excision developed the following facts: That, contrary to expectation, many of the duodenal ulcers involving the anterior wall had few of the characteristics of gastric ulcers. Ulcers in the anterior wall of the duodenum with obstruction and callus upon excision will often show a defect scarcely larger than a dimple. In the larger ulcers of the anterior wall the base is not often clean-cut and grayish white, like gastric ulcer, but more resembles a moth-eaten patch. Ulcers of the posterior wall of the duodenum present the same characteristics as those of the stomach, that is, a clean-cut, definitely punched out area, attached closely to the pancreas and usually completely perforating the duodenum. An anterior contact ulcer will usually be found just opposite the lesion on the posterior wall. They believe that excision of duodenal ulcers should be limited to those occurring on the anterior wall.

Acute Perforating Duodenal and Gastric Ulcers.—John B. Deaver reports twenty-five cases, of which in twenty-one the proximal duodenum was involved, in three cases the anterior wall of the pyloric antrum, and in one case the proximal jejunum. Recently ruptured ulcers of the duodenum and stomach bear surgery well, but after twenty-four hours the prognosis is usually hopeless. In these late cases he believes the patient should have the benefit of immediate operation, with rapid closure of the perforation and institution of pelvic drainage. He advocates, even in the presence of shock, complete operation in all recent cases. In ulcers of the duodenum the perforation is closed with a pursestring suture of linen, the ulcer bearing area infolded, and the duodenum plicated, if possible proximal to the ulcer. The operation is completed with a posterior gastroenterostomy. If the diseased area is in an accessible position it is excised, and plication of the duodenum and posterior gastroenterostomy performed.

Resection of One Third of the Colon for Irreducible Intussusception in an Infant Five Days Old.—Charles N. Dowd presents such a case, which he operated on thirty-seven hours after the onset of the symptoms. The five classical symptoms which presented in this case were: 1. A sudden attack of pain, accompanied by crying; 2. vomiting which could not be controlled; 3. blood from the anus, which appeared twelve hours after pain; 4. palpable mass within the rectum; 5. mass palpable by external abdominal examination. The writer believes that resection of the intestine is only to be undertaken when other measures have failed. Reduction by irrigation is dangerous. If the abdomen is opened the effort to reduce the intussusception should be made with the utmost patience and care. By pressing from below, the apex of the intussusception can be pushed upward, and the intestine will gradually unfold in about ninety per cent. of the cases. Even if cracks occur in the peritoneum the pressure and manipulation should be continued; peritoneal cracks can easily be repaired by stitches if the intussusception is once relieved. In the few cases in which reduction is impossible resection is the best course. If a resection must be done in babies, a two stage operation is to be avoided when possible. In the writer’s case the possible gangrenous spots made resection imperative. This left the cut ends of the colon held in clamps and well out of the wound. These ends were inverted by pursestring sutures, and a lateral anastomosis performed. Healing occurred without incident.

PENNSYLVANIA MEDICAL JOURNAL.
May, 1913.

The Bacteriology of Catarrh and Common "Colds."—A. Parker Hitchens concludes that "colds" are due to the activity of bacteria always present in the respiratory tract, which become pathogenic as the result of depression of external physical influences or internal derangements causing local venous stasis, and a weakening of the antibacterial properties of the mucus secretions. They may also be contracted by direct contagion from a person in whom the bacteria have become highly virulent through a period of uninterrupted growth. The rational treatment includes the relief of local congestion and the raising of the antibacterial properties of the blood and secretions by the use of a bacterial vaccine containing all the usual bacteria present in acute respiratory catarrh. Prophylaxis should include the control of physical conditions, improvement of general health, and the use of the vaccine as an immunizing agent. The vaccine contains the following organisms: the amounts stated being twice those for a dose:

- Staphylococcus ................................... 100 million
- Streptococcus .................................. 25 million
- Pneumococcus .................................. 12.5 million
- Micrococcus catarrhalis (group) ............. 12.5 million
- Bacillus Friedlander (group) ............... 12.5 million
- Diphtheroid ..................................... 25 million
- Bacillus influenza .............................. 125 million
OSTEOPLASTY.—John B. Murphy formulates the following series of laws which must be observed if one would meet with success in osteoplasty: 1. Normal periosteum completely detached from bone and transplanted into a flat or muscle tissue bed in the same individual, if he be young, may produce a permanent bone deposit, but only if osteoblasts remain attached to the lower layer of the periosteum. Normal periosteum rarely, if ever, produces a permanent bone deposit. 2. Strips of normal periosteum raised from the bone, detached at one end but left attached at the other, if turned out into the surrounding tissues, usually have bone produced on the under surface, at the osteoperiosteal angle, but not unless there are osteoblasts attached to it. 3. Normal periosteum transplanted into other individuals and contacting at one end with exposed or freshened bone rarely ever produces permanent bone. 4. When bone, with its attached periosteum is transplanted into fat, muscle, or other soft tissues in the same individual, and free from bony contact, is eventually absorbed except in cases of very young children or infants. 5. Free bone from which the periosteum has been attached, when transplanted into muscle or other soft tissues, always dies and is ultimately absorbed. 6. Bone with or without periosteum transplanted in the same individual and in contact with other living osteogenetic bone at one or both of its ends, always becomes united to the living fragments and acts as a scaffolding for the production of new bone of exactly the same size and shape as the original bone, provided the most perfect asepsis is maintained. 7. The graft per se does not possess any osteogenetic power; it merely serves an osteogenetic conductive purpose and is ultimately absorbed. 8. The musculo-tendinous attachments of the muscles should be sutured accurately around the graft at the point of desired union. 6. A bone covered at the end by cartilage, and at the sides by periosteum, such as the phalangeal bones, even when contacted with living bone dies, and is entirely absorbed.

PERIRENAL HEMATOMA.—John Speese presents the following conclusions on the subject of perirenal hematoma: 1. Perirenal hemorrhage is caused by tuberculosis, abscess, or tumors of the kidney, necrosis of the adrenal gland, and traumatism, and occasionally arises in hemophilia. The spontaneous form is probably due to chronic nephritis, the only pathological lesion which has been demonstrated. 2. The characteristic symptoms of the disease are sudden pain, the signs of internal hemorrhage, and the formation of a retroperitoneal tumor. 3. A moderate degree of hematuria is present in one third of the cases. Functional tests show diminution in the secretory activity of the kidney. 4. The affection is most commonly mistaken for intestinal obstruction or paraneoplastic abscess. 5. The disease pursues a rapid course if unrelieved, death resulting from hemorrhage, infection, or pulmonary complications. 6. Medical treatment has been uniformly unsuccessful. 7. Ten of the sixteen patients operated upon have recovered (sixty-two per cent). The mortality of the twenty-one cases treated by both medical and surgical measures is 52.5 per cent.

Proctolysis.—H. H. Trout presents an experimental study of comparing the effects of plain tap water as against normal saline solution per rectum in a series of over one thousand cases. The method of proctolysis is the same as described by Murphy, except in place of the hard rubber nozzle he employs a soft rubber catheter, and counts the drops per minute by means of a visible dropper. Extracts of the report are as follows: They have not been able to introduce the large amounts of water or normal saline solution such as Murphy reports (nine quarts in twenty-four hours), except in a few drainage cases. In seven cases of the series the following coincidence has been observed: A transient albuminuria remained in every specimen for two days after an anesthetic when using salt solution per rectum. Water was then substituted and at the end of twenty-four hours the albumin had disappeared. At this time a return was made to salt solution, with the appearance of albumin and a few hyaline casts in from six to twenty-four hours. Patients were then placed on a limited salt diet, and the urine in every case promptly returned to normal, and remained so until discharged from the hospital. Of the entire series 121 complained of thirst, and of this number 112 were salt cases. Furthermore, the water cases have taken one third more fluid by rectum than the salt cases, and the latter have required nearly twice as much water by mouth to relieve thirst.

Proceedings of Societies.

THE AMERICAN GYNECOLOGICAL SOCIETY.

Thirty-eighth Annual Meeting, Held at Washington, D.C., May 6, 7, and 8, 1913.

The President, Dr. Henry C. Coe, New York, in the Chair.

Uterine Inertia; Its Treatment.—Dr. George Tucker Harrison, of Charlottesville, Virginia, said that when the uterine muscle showed feebleness in the beginning of labor and during dilatation, this condition of atony was called primary uterine inertia. It was but one of the anatomical changes in the uterine muscle or to disturbed innervation. Secondary inertia was a condition of exhaustion which, from various causes, came on during the period of expulsion. Before rupture of the membranes, in primary inertia, there was no indication for active intervention. After rupture, if there were danger to life of the child from the discharge of liquor amnii, or the mother's life were imperilled from danger of septic infection, dilatation should be brought about by the metru-ryniter (rubber bag), and version followed by extraction then employed. In secondary inertia a too protracted labor was dangerous to the mother and child, and active intervention was indicated; if the head was well down in the pelvis and resting upon the perineum, the forceps should be applied. It recently had been proposed to perform Cesarean section in certain cases of uterine inertia, especially in the interests of the mother. The obstetric resources at our command are ample adequate, and there was no indication for such operative procedure in inertia per se. In primary inertia a combination of morphine, atropine, and strychnine often had an excellent effect when given hypodermically. After dilatation pituitary extract had found favor with some obstetricians. The exact field of application awaited further investigation.

Pituitary Extract in Uterine Inertia.—Dr. J. Clifton Edgar, of New York City, reported seventy cases of which records had been kept, and these cases were from two hospital services, Bellevue and the Manhattan Maternity, and
from private practice. They included in the first and second stages of labor, thirty-nine cases; immediately after the third stage, nineteen cases; in Cesarean section six cases; and for the induction of abortion six cases. He observed that 0.5 gramme of the drug alone should be employed, as, in his experience, constant results failed when the pituitary extract in bulk solution was used. 2. There were three reliable proprietary preparations of the drug now on the market; all of these were used at different periods in this series. For decided action, 0.4 gramme of the drug was usually called for, although in ordinary cases, with slight obstruction, half that dose was found sufficient. As the effect of the drug lasted but thirty minutes, repetition of the dose was of frequent occurrence. Often the use of the drug produced a palpable decrease in the resistance of the cervix, and on its removal, the uterine contractions were intensified, and a satisfactory progress of labor was generally obtained. Further, no toxic symptoms were observed from the use of the drug even in maximum doses. 6. Pituitary extract might be combined with ergot with the action of the former, failed, and with heart stimulants in shock cases, without compromising the actions of these drugs. 7. Pituitary extract had no place in normal labor; its administration in obstetrics should be confined to instances of prematurity and rupture of the membranes. Under these conditions the immediate pituitary extract or a propsect to the neighborhood and Cesarean section; in the last as a substitute for ergot. 8. The drug produced strong intermittent uterine contractions, often prolonged for several minutes. He had never observed true continuous tetanic uterine contractions in the case of the drug, premature separation of the placenta, and deep tearing of the cervix. In the first stage, or where some obstruction existed in the second stage, he gave the greatest of the drug, after complete delivery by means of the drug, in order to stop the hemorrhage and to bring the head in easy reach of a simple forceps operation. Seven of his thirty-nine cases were thus treated. 11. Pituitary extract acted promptly and efficiently in most of the cases. 12. In prematurity, the second stage, and the third stage. Its actions were more positive in multipara than in primipara; it acted better at full term than in premature cases; also better in the second and third stages of labor, and when administered shortly after the spontaneity of the membranes; in which cases he found no effect of the drug in two cases; it was necessary to use ergot in two instances; hot acetic acid douche in two more; to pack the uterus in seven cases; and retained placenta only when good uterine contractions observed. 13. In Cesarean section he found the drug could not observe any advantage of pituitary extract over ergot, aside from the observation that the former acted more promptly, and hence need not have been administered so early in the operation. In induction of labor the drug failed to initiate contractions, but apparently initiated them after the use of gauze, the bougie, or hydrostatic bag for inducing labor. His belief was that the drug strengthened already existing contractions not yet apparent, and that the membranes when ruptured in abortion cases his results with the drug were disappointing. For atony of the bowel and bladder and as a galactagogue his results were frankly negative. Those cases were in both infants and children. The administration of this drug for primary or secondary inertia of the first or second stage of labor must be reckoned with. Only a few of the thirty-nine cases of inertia actually were in the first stage of labor, and these were earlier cases. He does not consider the fact of the drug without line cases just merging into the second stage. He considered the use of the drug in the first stage a dangerous practice, liable to cause death or deep asphyxia of the fetus, separation of the placenta, uncalled for laceration of the uterus, and other complications. In the report of his thirty-nine cases of inertia in the first and second stages, two and probably four stillborn children, a result due, in his opinion, to the use of pituitary extract. In labor, the third stage, and for the induction of deep laceration of the cervix requiring suture to control the bleeding. He looked upon the use of pituitary extract before full dilatation, and until dilatation and the cervix were considered to be equivalent to the use of ergot at this time. In fact it was probably more harmful than ergot, by reason of the more powerful contractions produced, and the uncertainty of its action. He had repeatedly observed prolonged tetanic uterine contractions with this drug, the face of too much resistance, closely simulating tetanic contractions of the uterus (tetanus ulti). 21. The action of the drug was most uncertain. One could never predict in a given case, either from the amount of the drug administered, or from the time of its introduction to be overcome, how powerfully the drug would act upon the uterus. He had repeatedly observed in private and hospital practice that 0.2 gramme of pituitary extract, half the usual dose commonly employed, produced such prolonged and powerful uterine contractions that uterine rupture was imminent and anesthesia was required to control the action of the drug on the uterus. 23. In his opinion the drug should never be employed for inertia of labor unless anesthesia was at hand for immediate use and preparations complete for immediate operative delivery if necessary, to avoid uterine rupture. 24. Finally, with due regard to its action and possible dangers, pituitary extract was a most valuable adjuvant, as the resources for the treatment of primary and secondary inertia.

Under What Conditions Should Uterine Inertia Be Treated by Artificial Delivery?—Dr. Edwin B. Cragin, of New York city, said uterine inertia was of greater importance than in the stage of labor, especially if the membranes were ruptured and the placenta was separated. It came directly upon the child, than in the first stage; yet in several Cesarean sections performed during a prolonged first case the presence of meconium in the liquor amnii and the marked excitement and the fact that the operation had convinced him of danger to the fetus from uterine inertia even during the first stage of labor. Uterine inertia associated with fetal heart sounds indicating danger to fetal life was one of the first types of inertia indicating artificial and powerful uterine extract was studied, skilled, artificial assistance in the delivery before the mother and child were exposed to these dangers. There was one condition not usually classed as uterine inertia, to which the speaker called attention in closing. This was the long delay sometimes intervened between the rupture of the membranes and the uterine contractions of the first stage of labor. Patients sometimes presented themselves at the hospital with a history that the rupture of the membranes had occurred five or six days before labor began. An unfortunate experience several years ago in which the fetal heart ceased after the labor was completed, and a study of the temperature charts of a number of these cases, had convinced him that a large proportion of these cases were not due to inertia during actual labor; that there was fetal danger from interference with fetal circulation from prolonged pressure, and that maternal morbidity was common from sepsis, if not from infection. For these reasons he had made it a rule in recent years both at the Bellevue Hospital and in his private practice to introduce an elastic bag into the cervix if uterine contractions had not started at the end of twenty-four hours from the time of the rupture of the membranes, either in uterine inertia or in cases, not only brought on uterine contractions, but lessened the danger of escape of the liquor amnii, and the results both fetal and maternal had seemed to justify the procedure.

Dr. Edward P. Davis, of Philadelphia, stated that, from the stimulated external contraction, that pituitin that pituitin came into practical competition with strychnine, opium, and ergot, and Doctor Edgar had given very valuable hints as to the danger of pituitin. We all recollect that the heroic and unsafe course of treatment, the fact of the action on the nervous system, but not only the greatest value in bringing about the development of the physiology of labor, and we were all aware of the very frequent experience of the unexpected and rapid delivery of multiparae, half the time while lying on their back, and how frequently the woman surprised herself and us, most of all, when we were caught napping; but certain it
was that opium in the general experience of the profession was said to be wholly without effect on the ganglion which controlled the action of the uterus. As regards strychnine in comparison with pituitrin, it seemed to him that the difference between the two might be stated in this way, that strychnine, given in moderate doses, was a physiological stimulus to the ganglion stimulating and maintaining uterine action, while the action of pituitrin, especially as indicated by Doctor Edgar, was a matter of more brief and more stormy result, and hence much more uncertain; and personally, he had not felt that he could substitute the former for the latter, nor use the one as a aid in labor. The use of ergot was a thing to be carried out with great caution, and he still adhered to the belief that this drug should be given in the case of emptied uteri, with only rather moderate success, and that it should be laid aside ergot entirely with advantage. As to contrasting the dilating bag with the bougie as an inducer and promoter of labor in connection with strychnine or pituitarin, the former was of advantage in that it decidedly stimulated the mucous secretion of the cervix and was less apt to alter the mechanism of labor.

Dr. John O. Polak, of Brooklyn, New York, stated that no discussion of pituitrin in this society should go out without sounding a word or two of warning. He had had an experience of several weeks a few months ago with the use of pituitrin in connection with the uterus from the use of pituitrin. He had also seen within a month a woman that was thrown into such violent uterine contractions that anesthesia and morphine had to be used in order to control them. That experience, which was comparatively limited, only seventy-six cases, he had drawn the conclusions (which were, however, merely tentative) that pituitrin had little or no place in the first stage of labor; that it was of some value in the induction of labor, but this from his experience, which was comparatively limited, only seventy-six cases. He had drawn the conclusions (which were, however, merely tentative) that pituitrin had little or no place in the first stage of labor; that it was of some value in the induction of labor, but this from his experience, which was comparatively limited, only seventy-six cases. He had drawn the conclusions (which were, however, merely tentative) that pituitrin had little or no place in the first stage of labor; that it was of some value in the induction of labor, but this from his experience, which was comparatively limited, only seventy-six cases. He had drawn the conclusions (which were, however, merely tentative) that pituitrin had little or no place in the first stage of labor; that it was of some value in the induction of labor, but this from his experience, which was comparatively limited, only seventy-six cases.

Doctor Edgar stated that he believed he had the first instance. Dr. Edgar pointed out that this came into country. This was more than in a direct manner the cervix, because injuries to the cervix had been just as Doctor Edgar had stated. He had found, in addition, that it had no value, as far as his limited experience had gone. In establishing uterine contraction, in emptying the uterus in cases of incomplete abortion. Another observation he had made was that there was no dilatation during the third stage labor, he had gotten secondary relaxation in a sufficient number of cases to warn him that when he used it in the third stage it should be combined with ergot.

Dr. William E. Sturtevant, of New York city, said that one of the most important points in these three papers was that of calling attention to the dangers of pituitary extract. Enthusiastic reports sent around by the manufacturers have led to the use of the pituitary extract, with many unfavorable results. His own experience had been very much the same as that of Doctor Edgar. The pituitary extract was so uncertain in its action in the first stage of labor and was so apt to cause such bad results in cases of incomplete abortion. Another observation he had made was that there was no dilatation during the third stage labor, he had gotten secondary relaxation in a sufficient number of cases to warn him that when he used it in the third stage it should be combined with ergot.

Dr. William E. Green, of Boston, stated that these radical papers were going out to influence general practitioners, and in the subsequent discussion something ought to be said as to what should be done in the prevention of uterine inertia. The average woman who was going through a labor should be trained to...' and the ordeal just as men on a football team would be taught by a good athletic trainer. If this were done in a large proportion of cases there would be no inertia. Further more, the improved treatment of the women should be em-}
avoidance of contact of the sperm with irritated, senescent tissue. Finally, he considered the question of whether we should amputate the cervix before the cancer, and whether or not we should advise against marriage after the menopause.

The Menace of Cancer.—Mr. Frederick Hoffman, statistician of the Prudential Insurance Company of America, made an address on this subject in which he summarized the results of his investigation as follows: On the basis of trustworthy official data, it was safe to estimate the total number of cancer cases in the United States at 75,000 and in the civilized world at half a million. The cancer death rate in the United States was increasing at the rate of 2.5 per cent, per annum, and a corresponding increase was taking place practically throughout the civilized world. Age and sex differences in cases and death forms were fifty-nine years, or, respectively, 60.4 years for males and 58.2 for females. Cancer was largely a disease of adult life, and of the total mortality from the disease, 90.7 per cent, was at forty and over. The male cancer death rate in the United States in persons of twenty-five and over had increased twenty-nine per cent, during the last decade, and the female death rate, twenty-three per cent. On the basis of past experience, the distribution of cancer deaths in the United States during 1913 would be as follows: Cancer of the stomach and liver, 39,105; of the female generative organs, 11,235; of the rectum, intestines, and peritoneum, 9,688; of the breast, 6,817; of the mouth, tongue, etc., 2,830; of the skin, 2,670; and of other organs and parts, 11,688. These statistics fully substantiated the conclusion that cancer was a most serious menace to the American people, and that the tendency was toward an increase in the mortality, regardless of the cancer deaths prevented by early surgical operation. The cancer death rate of large American cities had increased from 37.2 in one hundred thousand population, during the five years ending with 1876, to 80.5 during the five years ending with 1911. The cancer death rate of the city of New York had increased from 37.5 in one hundred thousand population the period of five years ending with 1872, to 81.4 during the five years ending with 1912. The corresponding increase in the cancer death rate of Philadelphia during the same period of time had been from 41.3 to 101.1. In the State of Massachusetts, the mortality from cancer of the external organs for males had greatly increased during the five years ending with 1910 from a rate of 65.1. The corresponding increase for females, ages sixty and over, had been 54.9. The cause of these deaths had been in the mortality from cancer, there had been an increase in the mortality from biliary calculi in the registration area of the United States from 1.5 in one hundred thousand of population, in 1900, to 3.0 in 1911. All the facts available for the different sections of the country and of the principal cities throughout the world sustained the conclusion without qualification, that the menace of cancer was much more serious at the present time than it had been in the past. It should be stated, emphatically, that suggested the intelligent coordination of all possible agencies for the control of what had properly been called a national scourge and the deliberate reduction of the death rate of what was stated to be a preventable disease when subjected to early operative treatment. There was, therefore, urgent need for a national society for the study and prevention of cancer, and it was a gratifying fact that such a society was in course of formation.

President's Address: Pathology the Basis of Gynecology.—Dr. New York City, said our knowledge of tubal disease had made rapid strides through the aid of bacteriology. The etiology and treatment of pelvic suppuration, so familiar to every medical student, had been long obscured by the famous pair, pelvic cellulitis and periostitis. But however obscure, however subtle, and however obscure, however subtle, might have been the old pathology, we should not forget that the treatment was sound—to incise and drain a pelvic abscess through the vagina. When, with increasing boldness, they began to operate above the inflammatory affections, they paid for their experience at a fearful cost. Even the general practice of drainage did not avail, and in fact they now knew that probably the majority of the patients who recovered did so in spite of it. The necessary association of these operations was not found until it was discovered that malignant disease was an idea so firmly established that it was difficult to eradicate it from the minds of the profession, as well as of the laity. How many women with cancer had been allowed to reach the inoperable stage because of the absence of this symptom one dared not conceive. We were still in the dark as regards the etiology of various pelvic pains, when an opportunity was not afforded by exploratory section to verify a doubtful diagnosis of localized adhesions, twists of pedicles, or minor degrees of cystic and other changes in the ovary. More intelligent study of the parametria had shown that many cases were rejected as unfavorable for operation when the disease was really confined to the uterus, inflammatory exudate being mistaken for cancerous nodules. The limits of the radical operation had been greatly extended by Wertheim, whose experience and technical skill enabled him to deal with cases formerly regarded as inoperable. We are now in the very fortunate position of pathologists to discover the ultimate cause of cancer, and by careful experimentation to find a cure, either a serum or some metallic compound analogous to salvarsan. It could not be possible that the efforts of the many devoted workers in the laboratory and the operating room was concerned, these were essentially interdependent.

To be concluded—8

Letters to the Editor.

RIGHT SIDED OVETENSION AND PROLONGED TRENDLEBURY POSITION, EXCESSIVE ETHER, AND RAPID INTRAVENOUS SALINE INJECTION.

PITTSBURGH, PA., JULY 3, 1913.

To the Editor:

In the abstract of the chairman's address, delivered before the Section in Obstetrics, Gynecology, and Abdominal Surgery at the recent session of the American Medical Association, which appeared on page 1506 of the New York Medical Journal of June 28, 1913, I am quoted as calling 'attention to the greater operative risk of the patient whose heart muscle is weakened by various causes, such as hyperthyroidism, various toxins, anemia, etc. There is a possibility of such a heart being dilated by prolonged anesthesia; in which case the Trendelenburg position is to be resorted to and intravenous saline injections practiced.'

The use of the Trendelenburg position or intravenous injections of salt solution under such circumstances would be most reprehensible. They would very likely prove fatal. Kindly substitute my own summary of the paper which follows:

"Right sided overtension does occur as a postoperative complication. It is usually slight and causes no symptoms, but occasionally causes circulatory disturbances always with a rapid pulse. It rarely goes on to right auricular or cardiac dilatation. It is more likely to occur where the myocardium is weakened by disease. It may readily be precipitated or intensified by excessive ether, prolonged extreme Trendelenburg posture, or by the rapid intravenous injection of large quantities of salt solution while the heart is already embarrassed. It should be promptly recognized and treated by slight elevation of the head of the bed, a little morphine, and a saline injection."

F. F. SIMPSON, M. D.

TREATMENT FOR RECTAL FISTULA.

ST. CHARLES HOSPITAL, FORT PIERCE, FLORIDA.

JULY 5, 1913.

To the Editor:

Inject a one per cent. aqueous solution of formaldehyde.

1. Tell patient this will cause extreme pain for from three to five minutes, followed by local anesthesia.

2. Seat the patient, with the cephalic end of the fistula allowed free drainage. This will be necessary for a few days only.

II. In case of complete fistula one finger should apply
pressure on intestinal opening during injection, as this solution in the intestinal tract would cause unnecessary irritation, which, although not of great duration, would be extremely annoying for the time. If the solution is colored with aniline dye, the intestinal opening is readily found.

Remarks: This method has been satisfactory in all varieties of fistula: single or multiple; complete or incomplete; also in one case of perirectal and multiple fistula resulting from an infective process in the seminal vesicles. Here three treatments, with one week intervals, were necessary.

C. G. Roehr, M. D.

Book Reviews.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

The author presents a monograph containing twenty-four full page half tone illustrations devoted to the influence of vaccination as based on an analysis of 1,663 smallpox cases observed by him in England and port of Liverpool. It will prove of particular value to vaccine physicians, health officers, and others specially interested in the subject. Some of its interesting features are referred to editorially in the present issue. (See page 150.)

The first edition of this book showed its value, and this second appearance establishes its important position even more firmly than before. Much has been added to its worth by the addition of new material and the revision of that which had become old. The same emphasis has been placed upon the importance of an analysis of the sources from which the water has come, and warning has been given of the danger of laying too much stress upon the chemical and bacteriological analyses. Part one, consisting of six chapters, contains much of interest concerning which other materials have gained entrance to the water supply. The chapter on the bacteriological examination is very good. Attention is called to the necessity of using standard media and methods in all laboratories. Various simple tests may be obtained. Note is made of the fact that the nature of the medium, its reaction, the duration of incubation, and the temperature are all important factors in the development of water bacteria. Twenty-five plates are given which represent deposits found in water. This book can be recommended in every way to all those who are interested, directly or indirectly, in matters relating to water supplies.

As a result of both his laboratory and clinical experiences, Dr. Sophian occupies an important position that will fit him to write upon this disease. A careful perusal of this volume shows the great thoroughness and care that have been expended in reviewing the literature and presenting the subject. The first chapter deals, generally speaking, with the organism of the disease. The following chapters take up symptomatology, laboratory diagnosis, complications, studies of blood pressure, and treatment. Much value is added by the interpolation of illustrative cases and summaries of cases. The treatment of diagnosis and the treatment, are given in the detail that is essential for their proper performance: nothing of importance seems to have been omitted. Consequently, this volume can indeed be highly recommended as a very complete treatise on this serious disease.

The object of this work has been to present in elementary form an explanation of the phenomena of suggestion and hypnotism, to eliminate the misconceptions and prejudices commonly associated with them, and to make these phenomena serve as a key to value as means of diagnosis and treatment of disease. This aim has been well attained, and the result is a well correlated primer on the subject, which does not, however, consider the psychologic and psychopathologic experiences which are benefited by suggestion and hypnotism. It is as necessary for the physician employing these measures to understand psychology and psychogenic influences as for the surgeon to understand physiology and pathology, and it is to be regretted that the scope of the work was not sufficiently enlarged to include at least an outline of the psychogenic origin of disease.

Departing from the usual arrangement of textbook on diagnosis, this one is essentially an extensive tabulation of the entire subject of differential diagnosis of diseases of the nervous system, with the addition of many excellent drawings and plates. The first complete index serves as a key to the charts, rendering easily available the tables of differential diagnosis for each condition and disease, which can thus be compared or contrasted with associated or similar conditions, and the true relationships appreciated at a glance. What is lacking, however, is a corresponding text compensated for by the correlations, and the result is a book which, should be of much value, especially to the student, as an aid to the study of clinical neurology.

This pamphlet of 117 pages is made up of seven lectures, on the origin of disease and methods of prevention, delivered in the high schools of Hamburg. They have been given to a medical audience, they are of a somewhat popular character, but are well presented. In the first lecture, one deals with the factors of disease and immunity, the author takes the stand that our great knowledge concerning the causative agencies of disease has not come from the scientific side, and not at all from the clinical. He also adds that the public has the laboratory worker to thank for the newer methods of opposing disease. Of course, in so limited a space—no very detailed exposition of many subjects could be given, but these lectures present a good and interesting general review of the various topics.

The new edition of Lamb’s Diseases of the Throat, Nose, and Ear contains 328 pages of matter, a list of formulae for use in the diseases studied, and a very complete index. It is illustrated with fifteen plates, forty line diagrams in the text; there is an increase of twenty-eight pages over the second edition (published in 1909), and the book has been brought well abreast of the times. It is a work confessedly “for senior students and junior practitioners” and makes no pretense to being exhaustive. It is, however, written in so pleasing a manner, and the subject matter is considered in such natural a sequence, that it is a pleasure to go through it.
for purposes of review or of brushing up one's memory on this subject. It is an admirable book for the general practitioner; it will make his nose, throat, and ear cases more of a satisfaction to himself, and will show him when they had not best be referred to his confere the specialist in the limb. Four years of physical training and standing in a special clinic of this branch, Lamb's book will be of great help in telling what to look for and in explaining the meaning of what he actually sees in the examination of the patient. It is of decided merit and an extremely practical book.

Official News.

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers of the United States Public Health Service, for the seven days ending July 9, 1913:

McClure, G. H., Acting Assistant Surgeon. Granted two months' leave of absence, without pay, from July 15, 1913. Clark, T., Surgeon. Relieved from duty in charge of the Marine Hospital, at Evansville, Ind., and directed to proceed to Washington, D. C., and report to the director of the Hygiene Laboratory for temporary duty preliminary to final statement of trachoma and other diseases. Eager, J. M., Surgeon. Designated as representative of the government of the United States on the International Committee charged with the responsibility of conducting the International Office of Public Health in Paris. Gardiner, C. H., Surgeon. Granted one month's leave of absence from August 1, 1913. Lavinder, C. H., Surgeon. Directed to proceed, or to instruct Passed Assistant Surgeon R. M. Griswold, to proceed same duty, from time to time to such places in Georgia and South Carolina as may be necessary to collect data and material regarding pellagra. Lloyd, B. J., Surgeon. Detailed to represent the Service at the meeting of the Washington Medical Association at Everett, Wash., July 17, 1913. Tarbett, R. E., Sanitary Engineer. Directed to proceed to Cincinnati, Ohio, and report to Passed Assistant Surgeon W. H. Frost for duty in the investigation of the pollution of the Ohio River. de Valin, Hugh, Passed Assistant Surgeon. Relieved from duty at the Marine Hospital, Chicago, and directed to proceed to Roanoke, Va., for duty in the investigation of typhoid fever in rural communities.

Board of Convened.

Board of commissioned medical officers convened to meet at the Bureau of examination papers of assistant Surgeon C. M. Fauntleroy to determine his fitness for promotion to the grade of Passed Assistant Surgeon. Detail for the board: Assistant Surgeon General L. L. Cofer, chairman; Assistant Surgeon General W. C. Rucker, member; Surgeon B. S. Minkoff, recorder. Board of medical officers convened to meet at the Marine Hospital, Buffalo, N. Y., at the call of the chairman for the reexamination of an alien, Charles George Grainger. Detail for the board: Surgeon C. H. Gardner, chairman: Acting Assistant Surgeon W. L. Savage, recorder. Board of Medical officers convened to meet at the Marine Hospital, Buffalo, N. Y., at the call of the chairman for the reexamination of an alien, Anna Mikolayak. Detail for the board: Surgeon C. H. Gardner, chairman: Acting Assistant Surgeon W. L. Savage, recorder. Passed Assistant Surgeon H. J. Warner and Assistant Surgeon A. Kearney detailed as members of a Revenue Cutter Service Retiring Board to meet Monday, July 7, 1913, at 10 o'clock a. m., at the Division of Revenue Cutter Service, for the examination of Captain George M. Daniels.

United States Army Intelligence:

Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Army for the week ending July 12, 1913:

Armstrong, John M., First Lieutenant, Medical Reserve Corps. Ordered to active duty from July 14 to August 22, 1913, and will report on July 14th to the commanding officer, Fort Snelling, Minn., for duty until August 22d, when he will stand relieved from active duty in the Medical Reserve Corps. Baker, C. R., First Lieutenant, Medical Reserve Corps. By paragraph 7, Special Orders No. 121, Headquarters Eastern Department, ordered to Washington Barracks for temporary duty with W. B. Lieutenant Colonel, Medical Corps. Left Texas City on July 2d on one month's leave of absence. Beaven, C. L., First Lieutenant, Medical Reserve Corps. Relieved from duty at Fort Howard, Md., and will proceed to Fort Wadsworth, N. Y., for duty. Boyer, F. H., Major, Medical Corps. Left Gettysburg Camp on July 9th on leave of absence. Brooks, John D., First Lieutenant, Medical Reserve Corps. Ordered to active duty from July 10, 1913, to July 20, 1913, and report to the commanding officer, Fort Meade, South Dakota, for duty until July 20th, when he will stand relieved from active duty in the Medical Reserve Corps. Brooks, William H., Major, Medical Corps. Having been found by the Army Retiring Board incapable of active service, and such finding having been approved by the President, the retirement of Major Brooks from active service under the provisions of Section 1251, Revised Statutes, is announced; he will proceed to his home. Christie, Arthur C., Captain, Medical Corps. Will proceed to New York, N. Y., Fort Andrews and Fort Strong, Mass., on business pertaining to the investigation and installation of x ray machines at these stations, and on return from this duty to return to his status in Washington. D. C. Howard, D. C. Major, Medical Corps. Leave of absence extended five days. Keller, W. L., Captain. Left West Point on July 7th on twenty-one days' leave of absence. Kendall, W. P., Lieutenant Colonel, Medical Corps. Arrived in San Francisco, Cal., July 1st, for duty as Division Surgeon, Third Division. McCulloch, C. C., Jr., Lieutenant Colonel, Medical Corps. Relieved from duty at Fort McDowell, Cal., and will report to Washington, D. C., to grade the duty of the Surgeon General of the United States Army for assignment to duty as librarian of the Surgeon General's Office; the travel directed is necessary in the military service. Nichols, H. J., Captain, Medical Corps. Left the Army Medical School, July 9th, for fifteen days' leave of absence. Scudder, H. H., First Lieutenant, Medical Reserve Corps. Ordered to active duty and will proceed to Fort Howard, Md., and report in person to the commanding officer of that post for duty.

Births, Marriages, and Deaths.

Married.

Bigaman—Beard.—In Birdsho, Pa., on Wednesday, July 2d, Dr. C. E. Bigaman and Miss Florence Beard. Brown—Brown.—In Newark, N. Y., on Saturday, June 28th, Dr. C. A. Newcomb and Miss Minnie D. Brown.

Died.

Armfield.—In Meno, Ark., on Saturday, June 28th, Dr. J. M. Armfield, aged sixty-six years. Bohannon.—In Greenville, Ky., on Friday, July 4th, Dr. Jethro G. Bohannon, aged sixty-two years. Cornell.—In Lockland, Ohio, on Monday, July 7th, Dr. J. W. Cornell. Hyde.—In Everett, Wash., on Monday, July 7th, Dr. Everett Hyde, aged eighty-eight years. Jayne.—In Wallingford, Pa., on Tuesday, July 8th, Dr. Horace Jayne, aged fifty-four years. Lavenson.—In Los Angeles, Cal., on Sunday, July 6th, Dr. R. S. Lavenson, of Philadelphia, aged thirty-six years. La Bell.—In Deardeer, N. Y., on Monday, June 30th, Dr. Martin J. La Bell, of Elizabethtown, N. Y. Newell.—In Craf ton, Pa., on Friday, July 4th, Dr. Albert Arthur Newell, aged fifty-three years. Cincinnati, Ohio, on Wednesday, July 2d, Dr. Coleman Rogers, aged sixty-eight years. Sauer.—In Jersey City, N. J., on Tuesday, July 8th, Dr. Ferdinand N. Sauer, aged thirty-nine years. Smulyan.—In Salt Lake City, Utah, on Thursday, June 30th, Dr. John Smulyan, aged thirty-five years. Weeks.—In Portland, Me., on Saturday, June 28th, Dr. Ambrose Herbert Weeks, aged forty-five years.
Original Communications.

THE QUANTITATIVE AMINO (NH₃) NITROGEN CONTENT OF SYPHILITIC AND NONSYPHILITIC SERUMS.

Second Communication.¹

By D. M. Kaplan, M.D.,
New York,
Director of Laboratory, Neurological Institute.

The studies in the treatment of diseases caused by the spirochetes and allied organisms proved to the immunotherapeutists that in order to be able to produce a toxic effect upon this group of microorganisms the drug must contain a molecule for which the spirochetes display a definite positive chemotaxis. The substance used by Koch in his work on the trypanosomes was atoxyl, which, chemically speaking, is paraamidophenyl sodium arsenate and presents the following formula:

\[ \text{As}=\text{As} \]

\[ \text{HO-C}_\text{H}_3 \quad \text{HO-C}_\text{H}_3 \]

\[ \text{NH}_2 \quad \text{NH}_2 \]

Before the pentavalent As can act, it has to be reduced in the body to a trivalent As.

Another substance that proved of much greater utility than atoxyl was arsenophenylglycin, in which the As is trivalent before it is used in the infected organism. The chemical constitution is:

\[ \text{CH}_4(\text{NH}_2)\text{CO} \]

\[ \text{CH}_4 \]

\[ \text{As} \]

\[ \text{CH}_4(\text{NH}_2)\text{CO} \]

Still further study of the manner in which these drugs exert their influence on the invader prove that it is invariably necessary to have an amino (NH₃) molecule before the organism will take up the entire As carrying substance. In this connection the amino molecule may be regarded as the toxophore group of the drug, while the As represents the toxophore group.

¹See New York Medical Journal, June 7, 1913, p. 1172.

Copyright, 1913, by A. R. Elliott Publishing Company.

In salvarsan we possess an ideal chemical compound which has little effect upon the host, while at the same time exerting a most toxic influence upon spirochetes. In this substance the As is also trivalent, each arsenic molecule interchanging two valences with its partner. Its constitution may be expressed as follows:

\[ \text{As}=\text{As} \]

\[ \text{HO-C}_\text{H}_3 \quad \text{HO-C}_\text{H}_3 \]

\[ \text{NH}_2 \quad \text{NH}_2 \]

The substance mentioned above is an insoluble base, and before it could be utilized it had to be made soluble. The introduction of two CH molecules to the amino side chain makes the drug soluble and is the form in which it appears for use. This addition makes the entire chemical molecule a dioxydiaminoarsenobenzol dichlorhydrate.

As the avidity for amino (NH₃) is fairly definitively established by the observations of the action of the chemical compounds mentioned above on spirochetes it is not unreasonable to assume that the microorganisms have to have amino for their life and development. It is no more than natural that the invaded host has to supply this substance at its expense, and consequently suffers a loss of amino. It is also permissible to conclude that as the spirochetes are destroyed by the introduction of As, the amino content is permitted to increase and give greater quantitative results upon analysis. The nitrogen molecule that suffers in the infected organism is the amino (NH₃) attached in the (A) position to a primary aliphatic amino acid, which nitrogen is given off in toto in five minutes according to the method elaborated by Donald van Slyke. With the exception of glycoel and cystin, which also part with some of their CO₂, the amino nitrogen of the following aliphatic acids is given off quantitatively. Alanin, or alphaaminopropionic acid, has the following formula:

\[ \text{CH}_3 \quad \text{Leucin} \quad \text{CH}_3 \quad \text{Asparaginic acid} \quad \text{COOH} \]

\[ \text{CH} \quad \text{CH} \quad \text{CH} \quad \text{Asparaginic acid} \quad \text{COOH} \]

\[ \text{CH}_3 \quad \text{COOH} \quad \text{CH}_3 \quad \text{CH} \]

\[ \text{CH} \quad \text{COOH} \quad \text{CH} \quad \text{CH} \]

\[ \text{CH}_3 \quad \text{CH} \quad \text{CH}_3 \quad \text{COOH} \]

\[ \text{CH} \quad \text{CH} \quad \text{CH} \quad \text{COOH} \]
The deazotizing influence of the Spirocheta pallida is apparent in most serums from syphilitic individuals. This fact is offered only as another means of laboratory diagnosis, to be used in conjunction with the tests already in use. The ensemble of facts that establish the full fledged picture of syphilis in a neurological disorder are accepted the following: Somatic neurological signs of syphilis, a history of infection (these are the clinical evidences of the disease); the laboratory factors are, a positive Wassermann reaction in the serum, a positive reaction in the cerebrospinal fluid, an increased cell count, an excess of globulin and a normal reduction of Fehling’s solution. I wish to introduce the quantitative estimation of the patient’s serum for amino nitrogen as an additional corroborating measure, especially where the spinal fluid is normal and the Wassermann reaction in the serum positive. I would, in case the amino nitrogen content of the serum is normal, reserve decision until some other signs offer themselves before accepting the Wassermann result as significant of a previous infection. This is, of course, in cases where there are insufficient clinical evidences of lues. In a preliminary communication entitled, A Quantitative Chemical Reaction for the Control of Positive Wassermann Results (New York Medical Journal, June 7, 1913), the technical and the apparatus were described. In the studies of the present report the latest model of the Van Slyke aminometer was used, and, I must admit, with very little difference from the previous analyses, i.e., the syphilitic serums in the great majority of instances showed a marked diminution in their content of amino nitrogen, as compared with nonluetic sera. At present the following qualitative differences offer themselves: Manifestly positive individuals, clinically showing evidences of lues, with or without a positive Wassermann reaction in the serum, gave the following quantity in 100 c.c. of serum, 0 mg. to 2.8 to 2.9; patients clinically negative and in the majority of instances (only one exception) also negative serologically, 4.0 to 15.7. The intermediary figures of 3.0 to 3.9, inclusive comprise luetic patients reacting negatively and positively in the Wassermann test who were more or less vigorously treated, as well as patients who presented no signs of lues. If we should offer, for example, a patient whose serum resulted in a positive Wassermann reaction and who presented no physical or historical evidence of syphilis, and whose serum gave an amino content of over 4.0 milligrammes of amino nitrogen in 100 c.c. of serum, I would, on the strength of 472 corroborative analyses, exclude syphilis on that ground. Of course, it would require many thousand analyses before the value and the significance of this quantitative method could be established; at present I would advise the use of the method in instances like the one cited above. The clinical material, taking into consideration the results of the Wassermann reaction and the amino (NH₄) nitrogen content of the serum may be conveniently arranged into the following groups:

Lav. Virgin, twenty-six; headaches; no lues. 14.666

This last case is the only instance that I am able to offer at present where the Wassermann reaction was most likely faulty. I do not hesitate in the least in confessing to wrong reports on a small number of innocent individuals, which I hope will be cut down to zero with the use of the quantitative amino nitrogen method.
A glance at the tables given above is sufficient to establish the usefulness of the amino nitrogen determinations in serums where syphilis is suspected or where a positive Wassermann reaction is contrary to clinical findings. The differences between tables (A) and (B), on the one hand, and those of table (D) on the other, are convincing and need no comment. Tables (B) and (F) show us that the amount of amino nitrogen in the serum of a syphilitic remains diminished regardless of the negative Wassermann reaction. The factors necessary for the amino nitrogen to return and be present in a normal quantity as in table (G) are not known at present. A very important conclusion, however, can be arrived at from the observations stated above, i. e., that whereas the

Amino apparatus according to Van Slyke used by author; the barometer and the thermometer are not shown in the photograph.
amount of this substance present in the fluid is very small and inconstant. The amount varies from 0.3 in the nonlietic and may be present in the lietic to the extent of 3.6 in 100 c.c. It seems to me that no definite conclusions can be offered regarding its significance in the study of cerebrospinal fluids. Happily, we have other factors besides those stated above, and the Wassermann reaction to determine the lietic nature of a fluid. Before closing this communication I wish to present an analysis of a patient with an anxiety neurosis, who gave a positive Wassermann in the serum and a markedly diminished amino nitrogen content 1,136 mg. in 100 c.c. of serum.

PREVENTION OF DEATH AND RESUSCITATION.

By A. L. Soresi, M. D.,

New York.

(From Doctor Soresi's Laboratory of Experimental Surgery.)

The following brief notes are only an account of the work done in relation to "prevention of death and resuscitation," preceded by some considerations which will make the subject clearer, and may stimulate others to work along the same lines. It is generally admitted that there are organs, such as heart, liver, brains, etc., essential to the maintenance of life; severe injury or loss of which would cause death; while the loss or severe injury of other organs would not cause a fatal end. This assertion must be taken 

**cum grano salis,** and with the consideration that what we are compelled to admit to be a fatal injury at the present time may not be so in the near or distant future. So, if it is true that the loss, for instance, of the arms or legs, or of both, might not cause death, and the person who suffered the loss might live as long as if there had been no loss, this is due, in addition, to the development of our surgical technic, to social conditions. The same loss would prove fatal to a person isolated from other human beings, as he would be unable to gather food or to carry it to his mouth, and as a consequence would starve to death. Years ago it was thought that the stomach or the urinary bladder were organs essential to life; now we can safely remove or exclude these organs without immediate loss of life, although the person who suffers the loss is predisposed to immature death from poor digestion or ascending infection of the kidneys. Asphyxia, wounds of the heart, etc., were considered fatal only a few years ago, and are so now where the emergency facilities are not at hand. Up to the present day, a stab wound of the abdominal aorta, with its sudden and appalling hemorrhage, is considered fatal, but below experiments will be described in which life was restored, although for as long as nine minutes, the heart had already stopped beating.

When a person is declared dead, and is really so, it does not mean that all his organs are individually dead; the great majority of them could be transplanted to other individuals and under favorable conditions would live indefinitely. Life must be understood as the result of the harmonious automatic work of the organs constituting the body. The word automatic has to be emphasized, because the phenomena occurring when life is kept on artificially cannot be considered as life; for instance, a decapitated animal cannot be said to be alive, although it is possible to maintain circulation, respiration, and the digestive function for a certain time after the head has been severed from the body. This proves that each organ can live an independent life for a certain length of time, but that life is present only when the organs of the body are working automatically in a harmonious way, because each accomplishes certain functions which supply energies and stimuli to the others. It also shows the rôle of the nervous system to be that of the great coordinator of all the organs.

In certain respects the living body can be compared to an automobile. The automobile has in itself the potentiality of moving about, but unless it should move about independently it would not be considered to be a living automobile. To explain the comparison between the automobile and the living body better, it cannot be said that an automobile is functioning as an automobile should, if, instead of being driven by its own power, it is pushed or driven by a horse or another automobile. The machine is moving about just the same, but as an automobile it is dead; as soon as the outside driving power stops the car will also stop in exactly the same way as when the functions of the body are kept up artificially in headless animals. The automobile would also be dead if some essential parts were out of order. Suppose that the carburetor, the magneto, any part of the motor, driving shaft, etc., were not functioning properly, the machine might get along for a certain time, but sooner or later would come to a stop, and if the damage could not be repaired the automobile would be dead. All parts of the automobile might be in good condition, but the chauffeur intoxicated, or the steering gear not working properly. In such a case the automobile is alive; it can be driven by its own power, but very likely it will come to a sudden death, because it will hit against something and be demolished; the coordinating power failed to make the machine work as it should have done. The rôle of the nervous system in regard to the functions of the body corresponds to those of the chauffeur, steering gear, brakes, and wires in the automobile. A serious damage to the nervous system causes definite death because the organs, if they work at all, do not work harmoniously, each disturbing the other, until the harmonious automatic work ceases, and thus ends life. The importance of the nervous system can be well understood in cases of asphyxia for instance; there have been numerous cases of gas poisoning where the patient was brought back to life, with almost normal respiration, circulation, etc., but failed to live because the nervous system was damaged to such an extent that its coordinating power was lost. A very interesting case occurred to the writer while serving as a medical officer in the Italian army. A young man hanged himself with a piece of wire; when he was discovered there was no sign of life, neither respira-
tion nor heart pulsation could be detected. A piece of rubber tubing connected with an oxygen tank was passed through his nostrils, and rhythmic movements to induce artificial respiration were started. After about an hour respiration and heart action were almost normal, and to all appearances the young man was alive. If pricked with a needle he would react, but there was no consciousness and no pupillary reflex. Artificial respiration was stopped, and the patient put in an ambulance to be removed to the hospital. On the way there he was seized with convulsions, his body grew warmer and pulsations increased until they could not be counted. After he reached the hospital the convulsions stopped for a few minutes, but the pulse rate still increased and the temperature rose till the thermometer registered 43° C., the highest point it could register. The patient had several other attacks of convulsions, and his body grew warmer until he died, about three hours after having been found hanged. An autopsy, very poorly performed, did not reveal any special lesion.

This case is interesting because it shows that, although respiration and circulation had been reestablished, the patient failed to live because the nervous system (very likely the vagi nerves) had been so injured that it failed to coordinate the functions of the different organs, and the heart ran wild. In cases of this kind death results, and is caused by serious damage to one or more of the organs essential to life, or by the lack of control of the nervous system; the termination of life occurring when such damage cannot be repaired before the other essential organs have been injured too seriously, or the control of the nervous system be reestablished. Death occurs only when the heart is incapacitated for functioning, and the heart stops beating because the coronary vessels do not supply it properly, or the blood they supply is not fit to maintain in working order the cells constituting the heart. The ultimate cause of death is always asphyxia, anesthesia, or anemia of the heart.

In studying the subject of resuscitation, we will take into consideration only those cases where the heart has stopped beating. Resuscitation must be divided into two classes, temporary and permanent. Temporary resuscitation is obtained when, in order to keep up life, the essential organs must be artificially stimulated; as soon as the artificial stimulation stops, life also stops. Permanent resuscitation is obtained when the essential organs are stimulated artificially, but their lesions can be repaired, and at the stopping of the artificial stimulation they resume their automatic harmonious work. From the considerations now mentioned, it is evident that permanent resuscitation is not possible when there is an important discontinuity or degeneration of the nervous system.

The most difficult problem to be met in resuscitation is the reactivation of the heart's function. The technical difficulties concern the impossibility, at the present time, of entering the left heart without producing irreparable damage. If the left heart could be entered with some stimulating liquid as easily as the right, life could be reestablished without much difficulty. The reason is that the coronary arteries supplying the heart have their origin in the left side of the organ, and death being considered as asphyxia, anemia, or anesthesia of the heart, it is evident that better results than those now met with could be obtained if a technic of directly supplying the heart with a fresh, stimulating liquid which would wash out all the waste products and supply new stimuli could be developed. It is not an exaggeration to state that all cases of poisoning, of chloroform, cocaine, ether, chloroform, etc., as well as from asphyxia and hemorrhage, could be revived after the patients had been pronounced dead for a certain length of time, if the coronary vessels of the heart could be flushed with stimulating solutions. In these cases there is really no organic lesion, there is only a narcosis, asphyxia, or anemia of the elements of the heart. When there is also present an organic lesion this must be repaired, and success depends upon how well and quickly this is done.

In his numerous experiments, which will be given in detail in a later paper, the author found that the liquid that best stimulates and reactivates the heart action is blood. The most gratifying results have been obtained up to the present time in reviving animals dead from hemorrhage. A brief résumé of the results obtained may be of interest. Animals were bled to death by severing the femoral artery; artificial respiration was maintained by pumping air or other gas through the trachea; the thorax was opened and the heart exposed; when all heart beating had stopped artificial respiration was also stopped at times, and at other times kept up; direct transfusion of blood was resorted to through the external jugular vein; heart beating and life could be restored up to seven minutes after heart beating had completely stopped; no result could be obtained if instead of blood other stimulating liquids were used. Other animals were bled in the same way, but the thorax was not opened, and here heart beating and life could be restored after nine minutes after heart beating; respiration and all other signs of life had completely disappeared. The abdominal aorta and the ventricles of the heart were stabbed, and the animals allowed to die from acute hemorrhage; then the wound was repaired and the animals brought back to life as late as nine minutes after all signs of life had disappeared. Rapid repair of bloodvessels and heart were accomplished by a new technic devised by the author and not yet published. The technic is as follows: Small gold wires are bent so as to form an arc with two very small points in the inside of the arc; the intima of the cut bloodvessel is brought into perfect contact by squeezing the little gold wire, as is done for skin clippings; for the heart the clippings are double, so as not to cut the tissues during contractions. This technic is extremely simple, easy, and safe, because the points of the wire enter only the outer coat of the bloodvessels and do not penetrate the intima, so that there is no foreign body in the lumen of the vessels. Artificial respiration has been made either by simple traction on the tongue and pressure over the chest, or by a special pump, so constructed that the tube going into the trachea is airtight, and thus not allowing any escape of air between the tube
and the trachea. By a system of double pumping a given amount of air or any gas, alone or in combination, can be forced under a given pressure into the lungs and aspirated from the same.

In the prevention of death, the heart is always the important element to consider, as there can be profound coma or apnea without loss of life. The question is not one of stimulation of the heart as much as of saving its strength. In pneumonia, for instance, death could be prevented if the heart action could be kept up for a few days, the problem here being one of heart action only, because the disease exhausts itself in a few days. The heart is flushed with blood loaded with poisonous products, and while it is stimulating and nutritious element (the blood) is nourishing it poorly and poisoning it, it has to work harder, because of the resistance met from the consolidation of the lung tissue. With these considerations in view, the author has in two cases resorted to direct transfusion of blood into the external jugular vein after having bled the patients, and in another case, to continuous dropping of physiological solution into the external jugular vein. The results were very gratifying, but on account of the limited number of observations no definite conclusion will be made. In severe cases of hemorrhage death can be prevented if direct transfusion of blood, or at times even of saline solution, through the external jugular vein, is resorted to in time.

75 West Fifty-Fifth Street.

CHRONIC APPENDICITIS IN ITS RELATION TO HYPERACIDITY OF THE GASTRIC JUICE.

A Clinical Study.

By H. I. IILOWAY, M. D., New York.

1 CHRONIC APPENDICITIS AS A CAUSE OF HYPERACIDITY.

At the time when I published my first studies upon hyperacidity my suspicion as to the relation of the two to each other had already been aroused in the course of the observation made, but as it was my earliest observation, I regarded the pain in the appendicular region rather as a consequence of the hyperacidity than as the expression of an independent pathological process that had given rise to these self-same digestive disturbances.

Further and much more extended studies upon hyperacidity, with more numerous observations of chronic appendicitis in connection with it, have convinced me that the latter is in many instances the etiological factor in the production of the former. The following cases clearly demonstrate this.2

CASE I. January 16, 1898. S. L., clothing peddler, aged thirty-six; married; children. Weight 185 pounds (about 175 pounds net). Height five feet, six inches (short necked). Voice somewhat husky. Does not smoke. Does not drink (alcoholic liquors) at all. He enjoyed good health till about three years ago, when his bowels, which had hitherto been regular, became constipated, and, subsequently, other digestive disturbances followed. Now he complains that he becomes bloated immediately after eating and somewhat later feels a pain in the epigastrium that gradually extends downward into the abdomen below and into both hypochondria. He has always more or less burning in the stomach, and has a sour taste in his mouth. His appetite, on the whole, is good. He is a moderate eater, taking only two meals a day; he enjoys what he eats. His breakfast, taken about 9 a.m., consists of milk, bread and butter; his supper, of boiled meat and grits. Occasionally he takes a cup of coffee at noon. His bowels, as stated, are constipated, but he has periods of alternate constipation or even two stools a day, in the latter instance, regularly, very. He is much troubled with flatus. Occasionally he gets a pain in the right half of the abdomen, which runs up over the ascending colon and to the right half of the transverse colon. He is of a nervous disposition and, when he has a pain, he does not, as expected, he is very much upset. At times palpitations may set in, and they are more likely to occur when he is much bloated. He has a chronic laryngitis.

Examination. Epigastrium, nothing abnormal to inspection or palpation. No sensibility anywhere. No hemorrhage (placthemn). Water six ounces, no splashing, no sound. Liver and spleen normal. Abdomen, nothing abnormal to inspection or palpation. No sensibility to the right half of the abdomen, no pressure to the transverse colon. Heart and lungs normal.

January 18th. Ewald and Boas test breakfast; one hour; tube: when it had gone down about thirty-five cm. he became blue, cyanotic, his eyes bulged, he coughed in a hoarse manner, and I was obliged to stop the test. I draw it. I succeeded, however, in obtaining six c.c. of stomach contents, consisting of bread and fluid, the bread well worked up and the whole presenting the normal appearance. Reaction to blue litmus +, reaction to congo +. Reaction to trenicin (Boas) +, (markedly filtered, total acidity calculated on the residue for ten c.c.) sixty-nine.

Diagnosis. Hyperacidity of the gastric juice (possibly also a degree of subacute gastritis) and constipation. At the present time in the right half of the abdomen (which also, was not at all sensitive), this may be due to distention of the cecum and appendix by flatus.

Treatment. Dietary directions in accordance with the above findings, water, vegetables, toilet rule; cold drinking; massage of the abdomen. Medication, a tablet of one minim of tincture of nux vomica four times daily. January 23rd. The massage is proving effective. Bowels move twice daily; stools like pap. Directed to have boiled rice with his dinner (in the evening) and to thicken up the contents of the intestines and make them more consistent. February 6th. Has been getting along fairly well. Since three days mild attacks of intestinal colic. Yesterday, after his dinner at noon (he happened to be at home) he was very much bloated and his stomach quite puffed out. Some soreness in the epigastrium on percussion. Directed him to take two pancreoptaps tablets with each meal, and for the cramps I prescribed a teaspoonful of the mistura mixti et sodae with fifteen drops of Hoffmann's anodyne. February 24th. Since a day or two he again feels very much bloated after eating. Complains of pain over the transverse colon; has attacks of colic followed by diarrheal stools. Directions: Repeat the medicine prescribed and if after three doses of the last gets into this stomach the milk may be changed for any drinks or food cause no disturbance. There is some tenderness about the epigastrium, especially at and about xiphoid cartilage, on firm pressure and also, and more marked, over the transverse colon and over the ascending colon down to the line spina umbilicalis dextra. On the whole, however, his pains, he says, are not so severe as they were formerly, before he began treatment with me. The bloating is now more in his bowels. I prescribed an emulsion of spirit of turpentine, four drops to the dose, to be taken three times a day, and also a tablet of arsenic trioxide, grain 1/100.

2New York Medical Journal, May 25 and June 1, 15, and 29, 1902; Archiv für Veränderungen im Magen, 1902.

I have reported the cases in full, because an excerpt cannot show either the real development of the cases or their subsequent course. Moreover, an excerpt can be made to prove almost anything the reporter chooses.
three times daily; the patient to drink a glass of Vichy Celestins morning and afternoon; to eat nothing very heavy, all that is friable—cabbage, milk and eggs. A half cup of milk, as before—all that is friable—all but bread and butter. Warm. Breakfast, oatmeal, milk, bread and butter; lunch (at 12 noon), two soft boiled eggs, a cup of milk, bread and butter; dinner (6 p.m.), soup, broiled steak or broiled lamb chops; after dinner, a cup of chamomile tea. Milk, bread and butter. Lunch at 12 noon; dinner: a cup of rice and chicken, beef, milk and bread; breakfast: a cup of coffee, egg and toast, bread and butter; dinner: soup and crackers; supper, same as dinner. Bowels constipated.

Examination. Heart and lungs normal. Epigastrum, nothing abnormal to inspection or palpation. On hammering the epigastrum, some dullness has been detected in the region of the gallbladder and in the right hypochondrium, over the right colic flexure. No sensitiveness in the left half. Splenic, normal in size and position. Liver, normal in size, some sensitiveness to percussion over the right hypochondriac region. Tongue, lightly covered with a thin, yellowish white coat. General appearance good. Color of face dark, but not the slightest trace of a yellowish tint anywhere. Questioned as to the color of his urine, he said it was unchanged from what it was before treatment.

Since yesterday, the burning in his stomach is quite severe and he has a heavy pressure in this region. I did not introduce a tube; but sent him home, directing him to go to bed. A gastroduodenitis, involving the duodenum and common duct, had been set up. I prescribed an alkaline cooling mixture and ordered cold compresses to be applied over the abdomen (from the xiphoid cartilage to the pubes), and to have only milk and thin and oatmeal gruel. March 10th, he again visited him in his house, feeling somewhat better, but bowels moved this morning, the stool being partly light yellow and partly clay colored. Temperature normal. Prescribed a teaspoonful of the mixtura et sodae, to be given every three or four hours, until the pain has ceased altogether, to have also a teaspoonful of the liquor ammonii acetatis (recently prepared) every two hours, March 30th. He is still at home, and stool and complaint have given him no trouble. The yellowish tint of the body has entirely disappeared. His only complaint is now great pain in the lumbar muscles (rheumatic most likely; has had such attacks before: gets them more in the month of March than at any other time of the year). Prescribed sodium salicylate, ten grains, three times a day. To keep in the house for two or three days longer, after which he may go out.

He got along very well after this, and the last week in July he went to the country. About the middle of August he was seized one night with an acute attack of appendicitis, and was at once brought back to the city. The following morning he was taken to the hospital, where an operation was performed. In the history shows at once, what was not as clear to me at the time, that the whole trouble really lay in the appendix, and that the various intercurrent conditions related were all due in one way or another to the chronic appendicitis that was present. Two years later I had occasion to see one of his relatives, and learned that he had since been free from digestive disturbances.

Case II. August 30, 1905. M. P., private teacher; Russian Israelite; a resident of E., a small city in the vicinity of New York. Aged thirty-five; married; children. Height, five feet, four inches; weight, 120 pounds (eight weeks ago, 132 pounds). He smokes from ten to fifteen cigarettes a day; drinks a little whiskey two or three times a week, and is indifferent to form of alcohol. He is a man of good health. One hot day, about that time, he was in E., pursuing his calling; about 1 p. m. he took his lunch, consisting of several corned beef sandwiches. Later in the afternoon, when he got home, feeling very hot and thirsty, he drank nearly a whole bottle of very cold water, and then lay down on the oilcloth covered floor and went to sleep. He woke up after some hours with a headache and a severe pain in his epigastrium, more in the right side (B.), P., upper abdomen, in the form of a cramp, nausea and vomiting of undigested food. He at once took a dose of Epsom salt, repeated it every morning for three days, and, not getting better, sent for a physician, who gave him a hypodermic injection of morphine. The pain over the right half of the epigastrium and hypochondrium, particularly in the right hypochondrium, down to the line of the umbilicus, continuing, he sought admission to the hospital. He remained there for ten days and, not improving, he left. It is now eight days since he came out. The pain is still marked, he has a severe headache, [coffee, eggs, cold, bread and butter; dinner, soup and crackers; supper, same as dinner.] Bowels constipated.

Diagnosis. It is difficult to say at this date what the original seizure was. Inquiry did not elicit any satisfactory replies, as already indicated in the preceding history. He avers that the treatment he has received has not benefited him in any way. The fever was slight, having disappeared a few days before his admission. Comparing again the complaints with his general appearance and the results of the examination, the conclusion was almost forced upon me that the pains complained of at present were imaginary, the reflection of the pains he had during the weeks previous. I am partly agreed in this from what he said as to the indifferent character of the treatment he received at the hospital, that the physicians of that institution were of the same opinion nearly three weeks ago. However, in view of the location he assigned to the pain, and the sensitiveness to percussion over the liver, I assumed it as a basis for treatment a mild hepatitis.

Treatment. Smoking and all alcoholic liquors of what- ever kind, absolutely forbidden; half of starch and sugar, with the exception of milk and soft boiled eggs, which were allowed. To drink four or five glasses of water a day. To apply cold compresses (Priesnitzi), renewed every half hour, to the lower part of the chest and the upper half of the abdomen. As he must continue to remain during the day, he is to apply the cold compresses for three or four hours in the afternoon and evening. Medication indifferent. September 25th. Though to judge by his demeanor and his answers to certain questions, his pains must be relieved, he still complains of them, stating that he has pains on his right side (pointing to hypochondrium and region just beneath it). On percussion of the region described, a symptom resembling a surgical one was obtained, as of pain, saying it felt sore; a few minutes later, when I was going over the same region, he did not seem to notice it—at least made no complaint, as he had done before. He does not eat enough, and is directed to arrange his meals as follows: 7 a.m., two soft boiled eggs, a cup of milk, and one or two slices of graham bread and butter; 10 a.m., a glass of milk; 12:30 p.m., soup (vegetable) and rice or noodles; between 3 and 4 p.m., a cup of milk and one or two slices of graham bread and butter; 6 p.m., two soft boiled eggs, a cup of milk, bread and butter. To continue the cold compresses, applying them for two hours in the morning (6 to 8 a.m.), in the afternoon (3 to 5) and in the evening (8 to 10). Medication. Compound syrups, Epsom salt, boiled white rice, milk and bread, and milk and butter. To continue the cold compresses, applying them for two hours in the morning (6 to 8 a.m.), in the afternoon (3 to 5) and in the evening (8 to 10).
sensitiveness about the abdomen; no pain on flexion or extension of leg. Can walk and run without the least discomfort. The only complaint he has to-day is an uncomfortable feeling, when he turns in bed, about the transverse portion of the right costal arch border. Ordered to continue the application of the ice bag for two hours, after which he should have a cold compress on the more remote part of the gallbladder for four days; then at night only. Continue the same diet. Report again in one week. November 22d. An attack of lumbago; salol, fifteen grains, three times a day. Again some sensitiveness, though less marked, in the right hypochondriac region; feels it more when turning quickly on to his side.

December 18th. He complains again of the old pain at the point nine cm. to the right of umbilicus and 3½ cm. above it; it reaches to the costal arch border. To take a half an ounce of bromthymol and one ounce at bedtime. Examine the stool daily.

January 15, 1907 (8 p. m.). Patient has had another and very severe attack of pain in the region of the appendix. The whole right half of the abdomen is very sensitive to the touch; he has marked pain on flexion and extension of the leg. I directed him to go home and apply an ice bag and to-morrow to visit a surgeon with reference to operative intervention, which, in view of the number of attacks, I think advisable.

I did not see him again nor hear from him till June, 1910, when, becoming desirous of knowing the outcome, I had him looked up. I learned from him that, when he left my office at the time recorded above, he had gone home, taken to his bed, and had been under the care of Dr. H. A. McBurney of New York for two days; then felt better, and has continued well ever since, attending to an extensive grocery business, which he set up shortly after his last visit.

Case III. July 2, 1906. Mrs. J. C., aged twenty-eight, mother of three children; 17th, about three inches; height, a year ago, about 125 pounds; now 108 pounds. She was in good health till six months ago, when one day she was suddenly seized with a severe pain in the abdomen. She was sent to a prominent hospital here, was kept there for eight days, and then sent home. She had been told that she was afflicted with gallstones. She has grown much worse since and says she is now more yellow than ever. She vomits frequently, and when she does not vomit, belches much and right. It is much of her food.

The vomit is always very sour. She is on a light diet, soup, soft boiled eggs and toast. She drinks but very little water. Her bowels, always regular before, have been very constipated since her first attack. She has headaches. Her sleep has been poor. As she is too poor to keep help, and owing to her condition cannot do any housework, she has been compelled to break up her home and live with relatives nearly as poor as herself.

Examination. She is not yellow at all, only sallow. Her tongue is clean, with a small "strawberry" tip. From xiphoid cartilage to umbilicus, ten cm.; to crease (inscriptio tendinea), eight cm. Stomach: Left gastroenteric region dull; the whole epigastrium dull, sunken in, very little or less pain. Palpation near the center, not over the whole left of the epigastrium and in the median line, at a point 2½ cm. above the umbilicus. No splashing; water, eight ounces; no splashing; no sound. Liver: Normal, no sensitiveness over any part of it; nothing abnormal about the region of the gall bladder or spleen, nor- mal; kidneys, examination negative; abdomen, flat; no panniculus. Slight pain on percussion with hammer and on deep pressure in the right inguinal region. The pain is felt mostly around and about the umbilicus. She says there is a radiation from the right to the left side. Test breakfast; one hour; tube; sixty c. c. stomach contents, bread and fluid: bread in quantity about one fifth of the height of the contents of the glass; is well worked up in two layers; and two hours at night to the right.

Diagnosis. Hyperacidity of the gastric juice, giving rise to the gastric disturbances of which she complains. The constipation is but the natural consequence of living on concentrated foods—foods leaving but little indigestible residue. Chronic inflammation of the appendix, with probable involvement of the ovary.

Treatment. Dietary regulations in accordance with the
above noted conditions. Toilet rules. Sponge bath with cold water every morning. Medication: Pancreopepsin tablets with meals; five drops of tincture of nux vomica after each meal and before retiring at night; asafetida (H. Ewald) 10 cent. for twenty-four hours (for its carminative action upon the intestines and to cause free discharge of the flatus). 

July 10th. The bowels move daily. The pain in the epigastrium and right half of the abdomen is unchanged; there is no vomiting; you of course have not constipated, (with pain). Directed to keep as quiet as possible; apply an ice bag over the affected half of the abdomen; continue the directions previously given. July 22d. In statu quo. In view of the sensitiveness of the patient to proper lodging of her own, and therefore could not have the necessary attention and treatment, I advised her to have the appendix removed. 

She was operated on July 27th. The appendix was found adherent to the colon by numerous bands.

September 26th. Patient came in to-day to report that she is feeling well; is able to eat and work. Her husband has again taken a home, the family is reunited, and she is able to care for it.

The further history of this patient may not be without interest. October 3, 1908. Patient came in to-day. Has not been well for the last eight months; had an attack of grippe, which has left her in an enfeebled condition. About four months ago she expelled a tapeworm. For last three or four months she had a cough; rhinitis, pharyngitis, epiglottitis, and laryngitis (giving her voice a slight hoarseness), marked astigmatism and myopia, and right eye very much weakened. Since the birth of her son nine years ago, she gets cramps in her calves. For ten years she has had occasional attacks of sour stomach and would vomit her food. Two weeks ago she ate some herring and was seized with cramps. She treated herself with home remedies, and the cramps abated; but she continued to feel bad in her stomach. Three days ago she began to have fever, in her face more than anywhere else. She went to a physician, who prescribed some medicine which she was to take through a straw; it was very sour. Soon after taking it she began to vomit, and since then vomits frequently. The ejected matter is very sour. On the third or fourth day the vomiting became so violent that she threw up bile, and so continuously that she had to call a physician, who gave her at once a hypodermic injection of morphia. The night before last she had two soft bowel movements. On the second day she had a cup of milk, some bread and milk, and retained it, but the cramps came on after this. They seem to "draw her stomach together"; starting on the left side and passing over to the right. Her appetite is good and she generally eats every thing to which she and her people have been accustomed, especially much pickled and spicy foods. Lately, however, she cannot take anything sour (oranges, lemon juice) or anything sharp, like brandy; if she does, it at once burns or pains her stomach. Tongue, covered with a dyspeptic coat; bowels constipated; takes enemas to move them.

Examination. Epigastrum, nothing abnormal on inspection or palpation; not particularly sensitive anywhere. No masses or tumors. Stomach, very much distended, marked in the left half of the epigastrum. Liver, spleen, and kidneys in normal position; abdomen, good panniculus. Nothing abnormal on inspection or palpation. Marked sensitiveness of the skin over the umbilicus dextra, especially about the navel; lightheadedness, flexion, and extension.

Treatment, temporary, to relieve the distressing gastric symptoms: A powder of bismuth subnitrate, five grains, sodium bicarbonate, two grains, to be taken two hours before meals; and two grains, to be taken every two hours. February 21st. Patient feels better, does not vomit, only regurgitates a little of the milk. Still has some cramp, but not nearly so severe, nor so frequent. Gave her eight ounces of water, and then introduced a stomach tube; brought up up to the third or fourth tube coagulum. Reaction of the fluid to blue litmus +, to congo - Continue the powders, one every four hours now. In addition, ten grains of askatina, in pill, three times a day. Nourishment, a cup of milk (warm) with one-third lime water. Water is pouring out of the third or fourth tube, as before directed. February 22d. Test breakfast, Ewald and Bons; one hour; tube; obtained fifty c. c. stomach contents, bread and fluid; bread well worked up, all of ordinary appearance. Reaction, blue litmus +, congo +, phoroguced vinamin +. Free hydrochloric acid thirty-three, total acidity forty-seven. A deficiency in the hydrochloric acid element.

In IV, 1911. E., aged thirty-seven years, married; three children (three miscarriages); five feet, 5 inches; 195 pounds. Has muscular rheumatism; occasionally attacks of migraine. Chronic rhinitis, pharyngitis, and laryngitis (giving her voice a slight hoarseness). Marked astigmatism and myopia, and right eye very much weakened. Since the birth of her son nine years ago, she gets cramps in her calves. For ten years has had occasional attacks of sour stomach, and would vomit her food. Two weeks ago she ate some herring and was seized with cramps. She treated herself with home remedies, and the cramps abated; but she continued to feel bad in her stomach. Tongue, covered with a dyspeptic coat; bowels constipated; takes enemas to move them.
on pressure. Temperature in mouth, 100° F. As she had not improved under treatment, and in view of the increasing sensitiveness of the appendix region, the decision to operate was confirmed, and on the 21st she was admitted to the hospital, and have her appendix removed.

March 8th. I was informed that the appendix had been removed and that it was found to be in a state of chronic inflammation. March 13th. Patient came in to-day, and stated that after the operation she felt much better, but when she was allowed to eat and was given tea with lemon, sardines, etc., her acidity returned at once and she began to vomit again. On the ninth day, after a cup of black coffee and an egg, at 7 a.m., she began to vomit, and it continued intermittently. An examination of her stomach chemismus was made and a hyperacid condition of her gastric juice found. Still has some cramps about the left epigastrum, under the costal arch border. Does not vomit so much, but regurgitates a considerable part of her food; it comes up very sour.

Diet: Milk and soft boiled eggs. Medication: A peptic-pancratin powder with the eggs. Vichy (Celestins) with milk (half and half) at night before retiring. Bismuth ordered up to 5 drachms March 16th. Still had to change bag occasionally about the left epigastrium. Belches much. Bowels very costive. Ordered bismuth subnitrate, five grains, and tincture of nux vomica, half a drop, after each meal. A tablet of phenolphthalein at bed time, as required. Now vomits less, and her general condition is very well. Though she was out of the bismuth powders last evening, she had no flatulence, and did not feel any this morning; can leave them off. Continue the peptic-pancratin. Can have dry rice, the white meat of chicken, or fish after the operation. March 28th. On the morning of the 26th she had a cup of milk about 8 a.m., and two soft boiled eggs about 9 a.m. She drank a glass of water and immediately afterward began to vomit and had to change her bag. 1 p.m. she ate some dry rice and white meat of chicken; at 6 p.m. a cup of milk with an ounce of lime water and one soft boiled egg; about 9 p.m. she threw up again a little sour water. Slept well that night. Yesterday, the 27th, the vomiting stopped. At 8 a.m. she had a quart of milk and one egg, and felt well. Ordered suppository of codein, which I had previously prescribed for such an emergency; but the cramps did not abate till morning. Though the region of the sigmoid flexure seems to be the seat of the symptoms, it will be noted that the whole abdomen is involved. The abdomen is not at all sensitive now to percussion or palpation. To-day she is to take only warm milk (with a pinch of salt) or warm milk with one third or one half Vichy water, a cup of dry rice, or a tea bowl of chicken, once in two hours, every four hours. If the cramps should recur with any severity introduce a suppository containing one third of a grain of morphin sulphate. March 29th. Her sister brought the following report: She has some cramps still, but they are very much milder now. They come on only after the milk and Vichy. Directions: Leave off the Vichy. In place of the ordinary milk, use condensed milk. (The fresh condensed, as it is delivered here every morning), 1/2 teaspoonful in six ounces of warm water. Continue.

March 31. Patient is getting along well since taking the condensed milk. Yesterday, feeling that she needed an evacuation, she took two phenolphthalein tablets. They had the effect of clearing the bowel, and the cramps under the influence she had had about the rectum when costive. Still some pain about the epigastrum. Continue treatment. April 2d. Again complains of the sourness of her stomach and mouth. Has no cramps in abdomen, but feels some about the left epigastrum. Blotted and the matter thrown up was intensely sour. She had tried a little chicken soup, and it came up at once. Directions: Milk (as before directed), soft boiled eggs, fish (pike, perch, plain boiled). Bismuth subnitrate and extract of belladonna every four hours. April 4th. No more cramp. No sour stomach since taking the powders. April 9th. Doing very well, though she still has a slight sourness of stomach occasionally. As the fish have agreed with her, can now have whole piece of chicken. Ordered a powder of bismuth subnitrate, calcined magnesia, sodium bicarbonate, and extract of belladonna three or four times daily. April 21st. Doing very well. Take the powders only twice a day now, about 10 a.m. and 9 p.m.

May 21st. Patient feels quite well, and at this time her stomach appears fully recovered. She can take some vegetables, such as carrots and potatoes, and they agree with her. Her solute complaint now is constipation. Leave off all powders. Continue the olive oil, one drachm three times a day. She had ordered this a few days before, drink every day four or five glasses of fresh water, and observe the rules for the toilet.

Case V. February 25, 1906. Mrs. S. M., aged thirty-one years, widow, non-childbirth. Work in a storehouse. 5 feet, 3 inches. She remembers that as a girl, she had nervous indigestion, i.e., would feel hungry after large meals. The attacks would usually terminate in a hysterical outbreak. After that, dizziness. About the time of her marriage, at twenty-two years of age, these phenomena had disappeared, but she still had to be careful in eating. Sometimes a little whiskey would settle her stomach, and she could eat well. For a year and a half she has had heartburn continually. At first sodium bicarbonate or aspirin seemed to relieve her. Later on they failed, and only salt (ordinary table salt) relieved her (and quickly). The heartburn is now getting worse than ever, and she has it whether she eats or not. Whenever she is nervous or anxious it is especially severe. Occasionally she is followed by a feeling of partial indigestion.

Diagnosis. Hyperacidity.

Examination. From xiphoid cartilage to umbilicus, thirteen cm., to crease, eleven cm. Stomach: Left gastro-hepatic region, moderately distended, median line resonant to respiration; right epigastrum dull; no sensitiveness; whole crease dull; left crease about two cm. to left of umbilicus, somewhat sore. No splashing; water, eight ounces, no splashing. Liver, spleen, and kidneys in normal position, with no enlargement. On inspection or palpation: normal pancreas. She has a peculiar sensation in the right half of the abdomen, about the appendicular and inguinal regions; not a soreness, but a feeling as if it were stung by nettles. Occasionally, when walking, she puts her hands to her side to relieve this. There is a similar sensation, but less marked, in the left half of the abdomen. Flexing thighs on hip and extending it again rapidly do not cause any pain.

February 26th. Test breakfast: one hour: tube; eighty c.c. stomach contents, bread and fluid; considerable bread, well worked up. Reaction, blue hinius +: congous +: phlorogcin vanillin +. Free hydrochloric acid, forty-seven, total acidity sixty-nine. Pepsin, in four hours complete digestion. Rennet, in eight hours digested e.e. seventeen minutes. Diagnosis, hyperacidity; chronic appendicitis.

February 27th. Treatment as usual: Hard boiled eggs and milk. Milk and unboiled eggs. Milk and boiled eggs. Last Wednesday and Thursday she suffered greatly. Friday she felt a little better, and Saturday still better. She feels well when she eats heartily. The milk (which always has that effect with her) has loosened her bowels. She has four to five loose movements a day and evening. Last March 30th. She agreed to put cocoa in the milk in the morning for breakfast; at

1 Described in my book, Constipation in Adults and Children, etc.
2 Archives of Disease, etc.
other times to add lime water (one ounce to the cup). If she prefers, she can have a hard boiled egg at 10 a.m. and at 3 p.m., instead of milk. To take ten grains of bismuth subnitrate every day or two, and a teaspoonful of syrup peppermint in the evening. She continues to have her bowels. March 7th. Feeling much better yesterday and to-day. On Monday had a little waterbrash. Last evening ate a chop, and it agreed with her. Bowels better, only two or more times a day, now, and continue as before. March 20th. Has a slight pain in the right half of the abdomen. On examination, a spot about the middle of the right linea umbilicalis was touched she said it pained her, but when I went over the rest of the abdomen again, she found nothing was elicited. No pain on flexion or extension. Nothing abnormal to be perceived in the rectum. Has a slight heartburn occasionally. Continue as before. The pain in the right of the linea umbilicalis is probably ovarian or due to a flattened uterus. Ordered asaetic-tida, ten grains, twice daily, and to apply a cold compress (Priesnitza) to the abdomen. She has this pain when she gets excited or when she walks too much.

May 17th. Feeling very well. No heartburn or other trouble. Came in to ask whether she must still adhere to the diet. Told her she must do so for a year. As to the peculiar feeling in the right side, she still gets it when excited or when she walks too much. Continue the asaetic-tida as before. Continue the cold compresses in the evening. She has been three times this week. September 15th. She was very ill all summer at Ashbury Park, suffering from what appeared to be hay fever. Her nose is still stuffed, and she has pains in the chest and face, andVeronica is taking the drug hard, and these cold dry rhonchi; occasionally a mucous râle. Does not feel rested when getting up in the morning; her knees break under her; gets cramps in her calves. Muscles volatantes; black rings around the eyes. No elevation of temperature. She has never been abnormal in digestion. She has used Algesimeter four cm. This pressure excites a peculiar sensation, with a tendency to vomit. Light pressure on third dorsal and the vertebra below it causes a peculiar tingling sensation extending along the spine to the sacrum; great sensitiveness about the four details, ten general. Very little heartburn; bowels loose; four stools a day; general debility. Ordered a powder of bismuth subnitrate, cerium oxalate, and tincture of nux vomica, to be taken every four hours. Also quinine sulphate, three grains, twice a day. September 23d. Coughs less. Tongue, coated, pale, flabby; appetite only moderate; bowels in good condition. Pressure on epigastrium still causes the peculiar sensation noted. Ordered the above mentioned powder, three grains, every four hours. September 26th. The nux vomica is changed to sodium sulphate, one grain at a time, every three hours, and continues. Ordered potassium iodide three times a day, and, as a general tonic, strychnine sulphate, 1/100 grain four times a day. September 26th. Doing well; asthma relieved; bronchitis much better. Back also much better; sensitiveness over spine almost completely gone. Return of bowel weakness. Discontinue strychnine. Compound syrup of hypophosphites, one drachm three times a day. Continue other treatment. September 28th. Called up at midnight. Her bowels very loose. Ordered bismuth subnitrate, fifteen grains, and tannic acid, 2½ grains, every four hours. Has a severe coughing spell. Ordered half a grain of codeine, to be taken at once, and repeated in half an hour, if not asleep by that time. October 2. Patient called to-day. She had heartburn the day before. She had had a diarrhoea on the 29th. She had ten evacuations, and at night, about 11, a chill which lasted over an hour. Directed to discontinue the potassium iodide and the hypophosphite. Prescribed syrup of iodide of strychnine sulphate. Also tonic bath.13 October 2nd. Patient had heartburn after the iron mixture. Ordered potassium iodide in tablets, five grains, three times a day. October 17th. Does not react well after the cold douche at. Ordered bismuth subnitrate, ten grains, three times a day, more stuffed; voice rather thick. Continue treatment. October 29th. Not feeling so well. Took a fresh cold; her nose stuffed and sore. Quinine sulphate, five grains at three intermittent hour. October 30th. Feels much better this morning. Number of grains of legs. Paroxysm of lower extremities; static current.

13As given here in some of the hydrostatic institutes: Hot box (or electric cabinet), followed by rain bath and then the Scotch douche.

December 17, 1907. Has much gas in her bowels; occasional soreness in right half of abdomen; at times tendency to diarrhea. Ordered rice and peppermint tea; as a sedative pill (for gas). Tablets of potassium iodide for the asthmatic attacks (which have recurrd during the cold weather).

February 28, 1911. Has again trouble with her stomach. One evening four or five weeks ago she ate a hearty dinner followed by ice cream and two hours later was taken sick while at the theatre. Since then she has not been well. Last Saturday she became dizzy and was uncertain in her gait. She eats all varieties of food. Examination. Epigastrum: The whole of it very sensitive. Appendicular region: Linea umbilicalis vascular; no tenderness there. Teeth: Nothing in lower third; marked pain on pressure; she became dizzy when she lay down on the examination chair. Her tongue has a dirty grayish coat. Directed her to go to bed and take nothing but warm milk, a cupful every two or three hours. Tinguret of nux vomica, one drop every two hours. Should she have pain over the appendix, to apply ice bag. Prescribed the following: Sodi bromidi, 5; aq. distill. 3ij. M. Sig.: Two teaspoonfuls every four hours. March 6th. Feeling badly; weak; still dizzy when raising her head. Says she cannot take milk; is disgusted with milk food and must have meat. Ate chicken soup and it agreed with her. She looks pale and feeble; pulse very weak; has tendency to nausea. Ordered brenta. Strychnine sulphate, one grain at a time, every three times a day. Bismuth subnitrate, cerium oxalate and sodium bicarbonate, every four hours. Suggested appendectomy. March 10th. Feeling better, but still has pain in right half of abdomen. As long as the ice bag is on, she is relieved, but the moment she takes it off the pain reappears. Leave off the powder; continue ice bag and strychnine. March 12th. Telephoned this morning she is very costive. Ordered Rochelle salts, two drachms in half a goblet of water, to be taken every three times a day. April 6th. Patient was operated upon to-day; a chronically inflamed appendix; very much thickened, was found. Met her on the way home. Met her to-day. Still weak. Ordered compound syrup of hypophosphites, one drachm three times a day. She is to have appendix removed.

April 8th. Patient was operated upon to-day; a chronically inflamed appendix; very much thickened, was found. Met her on the way home. Met her to-day. Still weak. Ordered compound syrup of hypophosphites, one drachm three times a day. She is to have appendix removed.

More cases could have been added, but the few here recorded are sufficient. I believe, to prove my contention. It is not at all difficult to understand how a chronic appendicitis can be the cause of a gastric disturbance. It is a matter of every day observation that an irritation of the bowels of any severity can at once produce stomach symptoms—a nausea, if nothing more. In the graver forms of intestinal disease, as in intussusception, volvulus, etc., the gastric manifestations may become the most conspicuous feature of the case. The irritation from the affected portion of the intestine is carried upward and to the stomach through the plexuses of Auerbach and Meissner, through the splanchnic nerves from the thoracic ganglia and the filaments of the pneumogastric in the solar plexus. Whether violent muscular contractions in the small intestine can alone be held responsible for gastric symptoms, as, e.g., the nausea so pronounced in an attack of colic, is still a mooted question.

There is perhaps a peculiar feature about this transmission of irritations in the gastrointestinal tract that is deserving of note, namely, though the normal movement of the digestive tract, peristalsis, is
from above downward, from the stomach down to the very end of the bowel, and even the abnormal, the more hurried, the more violent peristalsis taking that course, pathological irritation is almost always transmitted upward from the intestines to the stomach, scarcely ever from the stomach to the intestines. The stomach may be most gravely affected, and the intestines still continue to functionate normally, apparently undisturbed in the least. This last point is of great importance in the consideration of our second group.

(To be concluded.)

OBESITY AND EMACIATION.*

By David BoVaird, Jr., M.D.,

New York.

All terms are relative according to the philosophers. Obesity and emaciation are peculiarly so. They would doubtless enjoy an application very different from that of Fifth Avenue among the Moors, whose ladies cultivate adiposity as the mark of feminine beauty, or among the Kelowis of Central Africa, whose bellies possess the weight and circumference of a young camel. But the Life Insurance Company of Basle brushes aside any such esthetic con-siderations and classes as doubtful risks any whose weight exceeds 530 grammes to the centimetre of height, or is less than 340 grammes to the centimetre.

Taking 1,000 grammes as equivalent to two pounds, and the centimetre as quarter of an inch, anyone may quickly determine the individual application of the discussion upon which we enter.

The causes of obesity (to take the larger subject first) may be readily classified as: 1. overfeeding; 2. deficient exercise; 3. alcoholism; 4. deficiency of certain internal or glandular secretions.

Overfeeding. Food is commonly spoken of as the fuel of the body, the coal whose burning (oxidation) supplies the energy necessary to maintain thought, action, and the varied internal activities of the body. But food also provides the building materials of the body. In the young a certain portion of the food is regularly consumed in increase of height and weight. In the adult skeletal growth ceases. "Which of you by taking thought can add one cubit unto his stature?" But many of us who take no thought find that growth in one direction is not denied us, and that we slowly but surely approach the model of Wouter Van Twiller, the famous Dutch governor of the New Netherlands, who, Irving tells us, was four feet, five inches tall and five feet, four inches about the waist. If we consistently consume more food than our bodies can oxidize and employ in some form of activity, the surplus is stored away in fat. That is nature's method of taking care of it. Just as long as the food is in excess of our needs, so long must the accumulation of fat continue.

Now, I know very well that in some quarters there will at once arise violent dissent or objection, and this or that person will be cited as evidence of the fact that one may eat very little and yet be over fat. True! We may even concede that there are certain differences in the physiology of the obese that render it possible for them to keep their weight on a smaller allowance of food than other persons. Indeed, certain experimental studies of the question seem to prove that that is the case. One may eat much less than some one else and still exceed him in weight, because the latter is working up the food he takes in some form of energy consuming activity, while the former is taking more than he works up and must store the excess as fat. But quantity is not the only factor of importance in this relation. The quality of the food must be taken into consideration. The sufficiency of any diet must be estimated on the basis of its chemical composition and the energy equivalent of the several food stuffs. The three great classes of food stuffs are the fats—butter, cream, oil, etc.; carbohydrates—sugar and starches, cereals, fruits, vegetables; proteins (nitrogenous or nitrogen containing)—meats of all kinds, fish, shell fish, poultry, etc. We are not to understand by this that vegetables are all carbohydrate and contain nothing else. All of them contain some protein, and some of them contain considerable quantities. In like manner, all the protein foods cited contain some fat and some carbohydrate in the form of sugar. It is only in the general sense that vegetables are classed as carbohydrates and meats as protein foods. The chemist, however, takes our several foods and accurately analyzes them in terms of the carbohydrate, fat, and protein that they contain. Thus:

<table>
<thead>
<tr>
<th>Food</th>
<th>Water</th>
<th>Albumen</th>
<th>Fat</th>
<th>Carbohydrate</th>
</tr>
</thead>
<tbody>
<tr>
<td>Cream cheese</td>
<td>30</td>
<td>0.65</td>
<td>0.23</td>
<td>0.55</td>
</tr>
<tr>
<td>Egg</td>
<td>74</td>
<td>0.12</td>
<td>0.46</td>
<td>0.57</td>
</tr>
<tr>
<td>White bread</td>
<td>33</td>
<td>0.70</td>
<td>0.46</td>
<td>0.35</td>
</tr>
</tbody>
</table>

The physiologist, in turn, has worked out the energy equivalent of these several foods, and expresses it in terms of what he calls a calorie, which is the amount of heat necessary to raise one gramme of water 1° C.

1 gramme protein = 4 calories,
1 gramme carbohydrate = 4 calories,
1 gramme fat = 9 calories.

Weight for weight, fat has two and a quarter times the energy of protein or carbohydrate. The physiologist has also calculated the caloric requirements of an individual at rest or at work. These requirements will naturally vary according to the weight and the activity of the individual. The pigmy requires much less than a giant; the thinker or the jeweler much less than a blacksmith. Thus, the physiologist has determined that the man at rest requires thirty calories per kilogramme (two pounds) of body weight each day; the hard laboring man may require fifty, sixty, even eighty calories per kilogramme. The total caloric requirement of an individual may therefore vary from about 2,000 to 4,000 or 5,000 calories a day. This cannot be supplied by any one kind of food, but means so much protein, fat, and carbohydrate.

Voit's figures are as follows:

<table>
<thead>
<tr>
<th>Bricklayer or carpenter:</th>
</tr>
</thead>
<tbody>
<tr>
<td>Protein ..................118 grammes.</td>
</tr>
<tr>
<td>Fat ..................... 36 grammes.</td>
</tr>
<tr>
<td>Carbohydrate ............500 grammes.</td>
</tr>
</tbody>
</table>

*Prepared at the request of and read before the Public Health Education Committee of the Medical Society of the County of New York at the New York Academy of Medicine, March 5, 1912.
in moderate quantities has a definite but limited food value. In large quantities its value in that direction is obscured by its toxic action. It may materially disturb the functions of the liver, increasing notably the excretion of uric acid; it may also produce degeneration of heart, arteries, and kidneys. In these relations it is no longer a food, but a poison. As a rule, therefore, the less alcohol an obese person allows himself, the better off he is. Total abstinence is for him the part of wisdom.

Influence of Sex. Women are much more prone to obesity than men, partly from physiological reasons; more largely from manner of life and habits of eating. The influence of child bearing upon increase of body weight is well known. In some cases, though a limited number, the menopause is marked by definite additions to weight and size. But in the large number corporulence results from excessive indulgence in candies and other sweet foods, and lack of sufficient bodily exercise.

David Graham Phillips's caustic elaboration of this theme in his Old Wives for New was not without adequate basis in fact. Men have been wont to satisfy their appetites with tobacco and alcohol, while women have been the patrons of the insidious manufacturers of sweets; but in these times of change this distinction may soon belong only to the past.

The Internal Secretions. There lie within our bodies various organs possessed of special secrections which influence deeply conditions of the organism. Time permits only the briefest reference to them at this point. The changes induced by child bearing and the menopause just alluded to are doubtless dependent upon modification of the functions of the ovaries, but the leading actor in the field of internal secretion has long been considered the thyroid gland, the gland which is situated just above the breast bone, in the median line of the neck, and whose enlargement gives rise to the familiar goitre. Deficiency in the internal secretion of this gland produces impairment of mental activity, sometimes amounting to stupor, and at the same time leads to notable increase of body weight, through changes in the subcutaneous tissues of the body. Under these conditions administration of an extract of the gland (prepared from the thyroid of sheep) will lead to marked reduction of weight, with loss of subcutaneous fat. For this reason the administration of thyroid preparations for the reduction of weight has of recent years attained more or less vogue, whether there are other symptoms of deficiency of thyroid secretion or not. Excessive doses of thyroid preparations may, however, produce very unpleasant symptoms, such as palpitation of the heart, nervousness, sweating, fever, and marked muscular weakness; so that its use should be accompanied by careful supervision.

There are other glands whose secretion influences the nutrition of the body and whose failure may lead to marked increase in flesh—notably the pituitary body. Living on the under surface of the brain and related in part to the thyroid gland we have just been discussing, and in part to the brain itself. Entertaining as the story of the pituitary is (and we are only beginning to know it)—excessive secretion on the one hand leading to enormous overgrowth of
the skeleton, especially the feet, hands, and cranial bones; diminution of the secretion leading to infantilism and adiposity—we can here only refer to it as another illustration of the profound influence exerted upon the body by structures until very recently supposed to have no definite function whatever. The pituitary comes too rarely into consideration, however, to justify more than mention of it at this time.

Treatment. The principles upon which rational treatment of obesity must rest have been indicated by the facts already presented. The essence of the problem is to reduce the daily intake of food below the level of the amount consumed by the activities of the body. This may be done in various ways. The diet may be reduced to a starvation ration, so that weight will be lost even by a patient resting in bed. "Leanness is attained by hunger; a treatment to produce leanness and a hunger cure are identical."

Debove's obese patient lost fifty-three kilogrammes (106 pounds) in less than a year on a milk diet alone (147 kilogrammes to ninety-four kilogrammes). Beginning with two and a half litres (five pints) a day, the amount was gradually reduced to one litre a day. This low allowance was persisted in for four months. A diet of vegetables, salad, and fruit was then allowed. Few physicians would have the courage, and still fewer patients the strength, to endure such an experience as that. Reductions to such a degree are rarely to be attempted; but if fat is to be lost the amount of food must usually be radically reduced.

To illustrate this point a table of analyses of standard antifat diets is here given. (Chart shown.) You will note that while they vary greatly in the quantities of the several foods allowed, they agree in that the amount of carbohydrates allowed is in all cases far below par, while protein foods are allowed in normal or higher amounts.

But whatever the composition of the diet, you observe that the total allowance is much below that of a normal individual at rest. If the individual subsisting upon any of these diets is called upon to make any exertion, the deficiency of his food allowance is proportionately increased. The amount of exercise demanded of any person undergoing a reduction cure must be determined by the physical condition of that individual. Some can endure heavy work on a deficient diet; others may be greatly harmed by any exertion. A thorough knowledge of the patient's previous history and a careful physical examination must precede any attempt to lay out a course of exercise for this condition. An athlete may "train off" five or ten pounds in a day without harm; a less vigorous person may be hurt by the effort to lose as much in a month.

Reduction of the amount of fluids (water) drunk is always a valuable aid in reducing weight, although it has little influence upon the amount of fat. In like manner the profuse perspiration induced by hot baths, Turkish and Russian, may reduce weight by withdrawing water. Such procedures are, however, limited in application to the very vigorous. The perspiration induced by healthful exercise is much more valuable, since fat is burned up in the process that induces the perspiration. Medicines have a very limited application in the reduction of obesity. Glandular extracts may be indicated in some instances. Occasionally thyroid extract may be helpful where there are no distinct evidences of deficiency of the gland, but the usefulness of these remedies is very limited. Often they have no effect whatever; occasionally, as already stated, they may be harmful.

To sum up the matter, we may say that the reduction of obesity must depend, in the main, upon a properly adapted diet and adequate exercise. The issue may be obscured by various devices, but the hard truth remains. For the overfat there is no royal road to leanness. Many strive for it, but fail entirely. Others succeed, but at such a cost of physical discomfort that they give up the fight, content to be fat and happy, rather than lean and miserable. A few succeed, and find the effort required well worth while.

Emaciation is most often the result of chronic disease of one or another type. Progressive loss of flesh should always call for careful investigation as to its cause. There remain, however, a certain number of individuals who persist more or less chronically below normal weight, yet without definite disease to account for the deficiency. In some families, as we all know, leanness is hereditary. Often these thin people are hearty eaters, and it is difficult to see the explanation of their meager weight. Time does not permit adequate discussion of the problem this evening. It is to be approached exactly as in obesity—as a problem in energy exchange, the amount of energy introduced as food, the amount expended in the various bodily activities. A disproportion exists between the two. To correct it we must pursue exactly the opposite policy to that we have just been discussing, i.e., the total amount of food must be notably increased, but more especially the carbohydrates and fats must be increased. Together with such modification of the diet, the bodily activity must be reduced till the point is reached at which accumulation of fat must begin. Once that point is found, it is usually possible by judicious increases in the diet to secure a progressive gain in weight. Here again we meet with individual peculiarities which are difficult to understand and overcome, but the fact remains that, in most cases of emaciation, attention to the relation of diet and exercise will lead to some definite improvement.

ON THE VALUE OF CAUTERIZATION BY THE HIGH FREQUENCY CURRENT IN CERTAIN CASES OF PROSTATIC OBSTRUCTION.

By A. Raymond Stevens, M.D.,
New York,
Assistant Attending Genito-Urinary Surgeon to Bellevue Hospital.

Since Beer's first report (Journal of the American Medical Association, May 28, 1910) of the possibility of cauterizing tissue in a water medium, and *ipso facto* the successful treatment of bladder tumors by means of the high frequency
current, this therapy has become quickly popular in dealing with neoplasms of the bladder. Its ready acceptance and employment by so many surgeons during the past three years is a commentary not only on its efficiency but on the case of application.

The idea of employing this method to get rid of obstructing tissue in certain instances of prostatic obstruction would seem to be rational, and, indeed, was suggested incidentally in Bee’s preliminary report. The absence of reports of such cases in the current literature prompts me to record the following two cases, in which the method was easily applied, with very little discomfort to the patients and with excellent results.

Case I. This man, forty-six years old, was first seen in January, 1912. He gave a history of moderate indulgence in alcohol, but denied venereal diseases. For over two years he had had frequency of urination with nocturnal enuresis, which conditions had become gradually worse. No blood had been noticed in the urine. For various reasons, he was under observation in Doctor Osogood’s service. The prostatic enlargement was probably symptomatic but had not been treated. By actual record, the patient voided every one to two hours, sometimes going three hours, the amount varying from two to eight ounces, the urine being always perfectly clear. Physical examination showed nothing abnormal except a hesitancy in the stream which was not regarded as of any consequence.

The prostatic border, viewed from the bladder side, was slightly irregular, but presented no intravesical lobes. There seemed to be some collarette formation, but this was not marked, as the ureteral orifices were situated at about the usual distance from the prostatic border. The bladder was markedly trabeculated, even on the anterior wall. A Wassermann reaction was reported negative. Careful examination revealed no evidence of spinal cord disease. By a process of elimination, the diagnosis of probable contracture of the vesical neck was made.

As a preliminary, a group of long villi found attached to the roof of the posterior urethra were quickly burned away by means of the Oudin current. Then, with the same technique employed in cauterizing bladder papillomatous tumors, a metal tip was placed on the neck of the bladder and a sterile insulated wire was inserted through the neck. With the use of the Oudin current, the neck of the bladder was cauterized, the tip of the cystoscope being placed in the neck of the bladder. The treatment was given at intervals of six or seven days each. No anesthetic was given and the patient was allowed to urinate as soon as his bladder was empty, and at no time as long as he ever did.

Summarizing, two cases of prostatic obstruction have been relieved symptomatically and objectively by high frequency current cauterization of the obstructing portion of the prostate. The residual urine in the case of contracture of the vesical neck was reduced from twenty-six ounces to one and a half; in the middle lobe case, from fourteen ounces to one half ounce. Both patients tolerated the cystoscope so well that no analgesia was used. The treatments were conducted in the office, did not interfere with the patient’s work, and were not followed by pain or serious bleeding. Probably the D’Arsonval current would accomplish results in such cases more quickly, but one must be cautious to avoid too deep destruction of tissue. With the Oudin current, after these and other experiences, I should be willing to do more at each sitting; thus requiring fewer cystoscopies.

Although there are but two cases reported here-with, the patients received such complete relief that it does seem that cauterization by the high frequency current must be considered as a possible means of treatment in dealing with certain types of prostatic obstruction—not with the uniformly large prostates, but with those instances in which the
offending part is localized and at the vesical neck; cases which are not relieved by prostatectomy or which may be so relieved but do not require this operation. About the same type of obstructions, so successfully relieved by the Chetwood or the Young punch operations, may probably be efficiently treated by cauterization by the high frequency current—namely, constriction of the vesical neck, median bars or lobes, and single lobes projecting into the bladder or urethra from any other portion of the prostate.

While this therapy, as I have used it, requires repeated application and hence would be feasible chiefly for patients tolerating the cystoscope well, it does not involve a skin incision, has not caused subsequent hemorrhage of any consequence, does not interfere with work, and does not require residence in a hospital.

40 East Forty-first Street.

THE RELATION OF ELLIS ISLAND TO THE PUBLIC HEALTH.

By Alfred C. Reed, M.D., New York.

A discussion relating to the public health of necessity requires an initial survey of the signification of the term public health itself. The term definitely refers to the sum total of individual and personal health conditions prevailing throughout the country, and connotes the presence of undesirable personal and social elements which are inimical to the continuance or attainment of public health. The modern scientific study of public health thus finds open to it two fields of activity, the one concerned constructively with eradicating a barrier of good health against the incursions of disease, and the other seeking to destroy the elements of disease by carrying war to the camp of its causes. Likewise the conditions influencing public health may be divided into two groups, domestic influences, such as endemic disease, social habits, racial, topographical, and climatic conditions, and foreign or external conditions, such as commerce, political relations and immigration.

Immigration ranks easily among the most important influences bearing on the public health. This relationship is many sided, intricately interwoven and inextricably entangled with numerous local or domestic conditions. Out of this great field certain phases of the relation of Ellis Island to the public health are selected for consideration because Ellis Island represents the vortex of the immigration movement. Of the million immigrants entering the United States yearly three fourths come through the gates of Ellis Island. Hence the problems of immigration center at Ellis Island, and it is here that the question can best be studied and effectual control of the situation worked out.

The opinion is general that un-sound aliens should be excluded. How to accomplish this most effectively and humanely is the central problem. The medical examination of alien immigrants devolves by law upon the Federal Public Health Service. Hence it is the duty of medical officers of this service to study every opportunity for improving the efficiency of their inspection. They should be leaders in the application of the most scientific and recent methods and discoveries to this field. The Public Health Service has no function which is more important than this. The national quarantine system is necessary and valuable, but the most essential feature of quarantine practice is in reality the medical inspection of immigrants, even though the two functions are now separated. At present there is insufficient coordination in the inspection at the different stations around the national boundaries and in the island dependencies. This is a most important point and deserves attention. Its bearing on the situation at Ellis Island will appear later. This condition could be remedied by a different administrative policy, by making the surgeon general of the Public Health Service directly responsible under the law for the efficiency of the examination and by actually requiring a definite system and routine of examination, together with certain definite physical and mental standards to be followed and applied in the medical examination of immigrants at all stations. Ellis Island is peculiarly adapted to serve as a centre for investigating and testing methods of examination. It should be a school of instruction for examiners, a great laboratory for the study of the physical and mental fabric of races and the determination of the actual importance of variations from these normals. It is an axiom of medical science that instruction, research, and skilled clinical practice go hand in hand with the best interests of the patient. So it is here. Ellis Island can only serve the best interests of the future America which will have absorbed the immigrants of to-day and to-morrow, when with the clinical care of its sick and the skilled examination of its immigrants, it combines a strong research department devoted to investigation of diseases and disabilities of immigrants both mental and physical, and the advancement of those lines of science which here may find material presenting of particular value.

The entire subject is new. No appeal can be made to precedent and experience, because precedent and experience are now in the making. It is an untried and very technical department of public health conservation. There are no definite standards whereby the mental and physical fitness of an immigrant may be estimated. These must be worked out at Ellis Island. This is impossible at present for two reasons: The staff is too small and the administrative policy is passive, rather than aggressive, reactionary rather than progressive. These two reasons may have foundation in necessity, but nevertheless the facts stand. Popular recognition of the situation is growing, and with it popular demand that the responsibility be placed. It is not the immigrant aid societies, nor the large national societies, nor the employers of foreign labor, nor above all the steamship companies, which hold the controlling interest. It is the American people, and the interest of the American people requires that the medical staff at Ellis Island be sufficient in numbers, as it is now in ability, to do more effective work in certain definite directions, and that the administrative policy encourage and accomplish cer-
tain definite objects in the line of scientific medical investigation and the application of the best scientific methods in the examination of immigrants.

It is easy to illustrate the abundance of subjects at Ellis Island awaiting detailed investigation. Trachoma is proving itself a national health problem. A survey of 30,331 Indians last fall showed 22.7 per cent. to be trachomatous. At this rate there are 72,000 cases of trachoma among the American Indians. McMullen found that 12.5 per cent. of 4,000 mountaineers in Kentucky had trachoma, and believes a similar condition to obtain through the mountains of Virginia, Carolina and Tennessee. Foster found seven per cent. of 1,304 Alaskan Indians to have trachoma. The New York city board of health has recognized the undue prevalence of trachoma in school children and has instituted careful investigations to help solve the problem of its control. At Ellis Island there is no feature of the medical examination which is more thorough and painstaking, and where a higher efficiency ratio is maintained than in the examination for trachoma. Rare skill and judgment are exhibited in the detection and treatment of this condition. This excellent trachoma clinic, however, should furnish material for continued investigation directed toward elucidating the etiology, predisposing causes, and positive diagnosis of the disease, as well as the determination of its means of spreading, and of better methods of treatment, prevention, and specific cure. Here is a national health problem of menacing proportions, and the results obtained from the study of the disease at Ellis Island would have a wide field of application.

The hookworm has leaped into prominence, especially since the invaluable surveys and clinical activities of the Rockefeller Sanitary Commission. Here is another public health problem of great importance. Hookworm infection belts the earth in a zone sixty-six degrees wide, extending to thirty-six degrees, north latitude. It is found abundantly in eleven of our own southern States and to a lesser extent in several more. Many immigrants come from the infected zone. How can the infection be eradicated in the United States, no matter what the expenditure of time and money, if a constant stream of fresh infection is pouring in through Ellis Island and the other immigration stations? Manning found that 0.4 per cent. of the hospital patients he examined at Ellis Island harbored the hookworm. If a routine examination were made of a series of cases coming from the infected belt alone it would be justifiable to expect a far higher proportion. It is certain that a survey of the relative prevalence of hookworm in different races and nationalities at Ellis Island would give definite data on questions of incidence and effect, and would incidentally facilitate the cure or exclusion of all cases in immigrants, as the law now very properly requires.

There are besides, most pertinent problems in connection with this disease for the solution of which Ellis Island affords advantages. Among these problems may be enumerated the question of the relation of hookworm infection to external and recognizable signs and symptoms, the question of the effect of the infection on the cardiac and other systems and on the susceptibility to other affections, the question of the association with other parasites, and the question of the elaboration of better methods of diagnosis. A most important question is the determination of a safer and more efficient method of treatment, as also a study of the life cycle of the hookworm and its manner of infection.

It has been the endeavor by these two instances to illustrate the great importance for the national public health of instituting scientific clinical and laboratory study of the diseases of immigrants at Ellis Island. The results of such study would be available for application in two directions. In the first place, these results would be applicable in combating and preventing existent disease in this country. In the second place, they would facilitate and measure a vastly improved and more accurate system of immigrant inspection. These illustrations by no means exhaust the list.

It is recommended in the annual report of the Public Health Service for 1912 that there be established in New York a branch of the Hygienic Laboratory in Washington. This recommendation deserves the fullest support and should eventuate in an ample appropriation by Congress for this purpose. When it is remembered how significant a role the laboratory plays in modern medical diagnosis it is remarkable indeed that the medical staff at Ellis Island, unhampered as it is, should do as effective work as it does. Carriers of typhoid, cholera, hookworm, and other intestinal parasites may be in apparent health. Detection of these maladies rests solely on laboratory evidence. The diagnosis of syphilis without a blood reaction is often most uncertain. Blood cultures and serum reactions in this and other diseases are indispensable for good diagnostic work. Routine urinalysis, blood count, and ophthalmoscopic examination are considered essential in ordinary hospital and private clinical practice. They are even more essential in the examination of immigrants in the primary inspection at Ellis Island. No matter what the reasons for these deficiencies, they ought to be remedied. The Public Health Service is deputied by law to conduct this examination. The examiners should employ every resource of medical science in their work. The work is highly technical and extremely difficult—far more difficult in fact than can be realized by anyone who has not participated in it and experienced the peculiar handicaps and impediments incident to the medical examination at Ellis Island. This peculiar difficulty, as well as the unique responsibility devolving upon the medical examiners, require indeed that he bring to his assistance every needed art of medical and scientific practice, for even then he will no more than fulfill his function of guarding the public health from hostile influences entering in the stream of immigration. Whether the fault lies with Congress, with the administrative bureau, with the superior medical officers at Ellis Island, or with the medical staff, is not in the province of this paper to determine. The medical profession has a responsibility derived from its training, its function and its heritage, to require the very best possible protection of the public health at every strategic point. Hence its necessary interest in securing the very best medical inspection of immigrants at Ellis Island.
Turning to a somewhat different aspect of the medical examination at Ellis Island, there appears an opportunity and, in fact, a necessity for a careful tabulation of a large collection of data on both normal and abnormal individuals of the various immigrant races, with the object of determining practical standards of mental and physical normality for each race. Here again two attitudes are reasonable. We may set a standard of admission based on average normal American characteristics, drawn from studies of native born Americans of native parentage. On the other hand, we may establish an admission standard based on the average normal characteristics of each race seeking entrance. Space forbids discussion of this question further than to say that its settlement can not be arbitrary. Before a decision can be made it is requisite that we have data showing the actual normal standards of each immigrant race. If any importance at all is to be attached in the examination to racial standards of normality this data must be had. Certainly, therefore, it is necessary to make a careful study and record of the physical types, development and mental characteristics of a large number, preferably several thousand, of normal individuals of each immigrant race. From such records can be deduced fairly exact standards of physical and mental normality for each race. By comparison in the actual examination of each immigrant with this standard a more accurate judgment can be made as to his mental and physical normality as quickly reached as to the relative normality of that individual. Two illustrations may be given of the applicability of such standards, and the facilitation thereby of the immigrant examination.

The immigration act of 1907 contains the excellent provision that certain conditions which are not specifically excluded, but which affect the ability of the immigrant to earn a living, should be certified as such by the medical examiner, and that such cases shall be considered by the board of special inquiry of the Department of Labor, to determine if admission is permissible. Under this class of certificates are many inscribed “deficient in physical development corresponding to age and race.” “Road 1912, of a total of 7,067 certificates issued by the medical examiners at Ellis Island, for all causes, for poor muscular development, 444 for malnutrition. Especially among Armenians, Hebrews, Gypsies, and Italians is this question of relative physical importance. No racial standard of normal physical development is available, but such a standard can be obtained by taking a series of from one to ten thousand normal individuals of each race and recording their physical measurements, including height and weight. Such a standard need not be a fixed absolute rule of thumb. But it will afford us a means of picking out the physically defective of available at present, a portion of the physical by defective could be detected by using it a larger proportion than by the present haphazard method, which is dependent on the personal equation and individual views of each examiner.

Our second illustration is taken from the much debated question of the detection of mental defectiveness in immigrants. To a varying extent insanities, especially of the functional group, can be included here too. It is manifestly impossible, even with a good interpreter, to judge a Russian peasant, a Sicilian vined, a Dalmatian mountainer, a Basque from the Pyrenees, an illiterate Irishman, a West Indian negro, by the same tests or to expect the same reaction to questions and to stimuli as with an American. The Croat, the Pole, the Lapp, the Bulgar, the Italian and every other race has its own peculiar heritage of racial customs, history, and environment. Each has a more or less distinctive and distinct manner of thought, standard of living, degree of mental alertness, and acquaintance with physical and spiritual phenomena. Heredity and environment of so different a nature have contributed in each case to the development of different personal and mental attributes.

The present vogue of the Binet-Simon measuring scale of intelligence does not justify it as a standard for estimating the mental development of immigrants. This scale was formulated from and for French school children. The principle involved in it, however, may be taken over with advantage in the elaboration of measuring scales of intelligence for each immigrant race, at least until a new and more satisfactory principle can be evolved. But the fact remains that a standard of mental normality for each race is a fundamental need. The lack of such a standard makes difficult the certification, and especially the detection, of many cases of mental defectiveness in immigrants. The availability of such standards would facilitate in some degree, too, the even more difficult detection of certain insanities. In considering the mental examination of immigrants, it is to be recalled that as a rule this examination must be through the medium of interpreters. The lack of enough good interpreters is now one of the great handicaps in the mental examination at Ellis Island. It is of lesser moment whether the interpreters are to be provided by the Department of Labor or by the Public Health Service, although the latter plan seems to have distinct advantages. The important question is that more interpreters are badly needed and debate as to which department should furnish them ought not to delay longer their being provided. A beginning has been made in the matter of relative normal standards of immigrant races at Ellis Island by Dr. M. K. Gwyn, who has conducted a series of anthropological measurements under the instruction of Doctor Hrdlicka of the Smithsonian Institution. This work is a valuable beginning and should be extended to other lines. Improved methods and standards of examination which have been worked out at Ellis Island should be followed at all immigration stations, and the work in all should be made uniform and mutually consistent. The interests of the national public health require efficient exclusion of physically and mentally unsound immigrants. In addition to the considerations already discussed, the medical staff at Ellis Island is hampered in conducting such an examination by lack of sufficient men and lack of proper quarters and facilities for work. On ordinarily busy days the present quarters are insufficient.
crowded, poorly ventilated, and inconveniently arranged. The mental examination, particularly, is handicapped by absence of quiet sanitary examining rooms and of facilities for observation of cases. In hot weather conditions are measurably worse. The medical division is poorly adapted in arrangement, facilities and sanitation for its functions. As a result of the lack of sufficient men and facilities, and possibly of proper direction, the efficiency of the examination at Ellis Island is apparently below that of Boston, Baltimore, and Philadelphia, which rank next to New York in amount of immigration. The class of immigrants at these four ports is fairly comparable, being drawn in general from the same localities and races. In fact, any difference in this respect is in favor of New York receiving a poorer class of immigrants than the other ports, in which case New York should show a higher proportion of certificates for physical and mental disability. In the tables appended, Class A1 includes idiocy, imbecility, feeblemindedness, epilepsy, insanity, and tuberculosis. Class A2 includes loathsome and dangerous contagious diseases. Class B includes disease or defect affecting ability to earn a living. Class C includes minor disabilities. In Table 1 are stated the relative numbers certified in the respective classes at the four ports in 10,000 immigrants examined. Table 2 gives the relative standing of the four ports in number of certificates under each classification, as shown in Table 1. The last column gives the sum of these relative standings and places Philadelphia first, Boston second, Baltimore third and New York fourth.

Space has permitted consideration of but a few features of the importance of Ellis Island for the public health. While these features have been discussed critically, it has been the endeavor to make the criticism constructive. Simple iconoclasm defeats its own end. There are still many points to be taken up, as, for instance, the relation of Ellis Island to the New York State quarantine, the relation of immigration inspection in general to national quarantine, the medical inspection of alien cabin passengers on board ship and the supplementation of the Ellis Island examination by a rigorous enforcement of a deportation law in cases exhibiting certain diseases or defects after landing. On the other hand, much can, in simple justice, be said of the ability and efficiency of the men engaged in the actual work at Ellis Island. Some of their handicaps have been pointed out. Compared with an indifferent inspection, their work is highly efficient; but compared with the best possible efficiency there is yet much to be desired. Certain faults exist and ought to be eradicated. The awakening public health sense of the country demands that the medical examination be the best attainable. This awakening is merely an instinctive national protective reflex, based in sound reason and operating to conserve American public health, both physical and mental, and that type of culture and ideals which is distinctively national.

THE MENTAL MEASUREMENT OF FOUR HUNDRED JUVENILE DELINQUENTS BY THE BINET-SIMON SYSTEM.*

By William G. Eynon, M.D.,

New York,

Attending Physician, New York House of Refuge; Assistant Visiting Physician, New York Red Cross Hospital.

This work has been done at the New York House of Refuge during the past six months. The Binet-Simon tests, as revised by them in 1908, have been used, and record cards employed like the ones devised and used by Goddard. The subjects were all males between the ages of eight and twenty years, inmates of the House of Refuge, where they had been committed for offenses ranging all the way from incorrigibility to felony.

The objects of this work might be grouped roughly into three divisions: First, to ascertain as nearly as possible how many of these boys, who have been arrested mentally for a variety of reasons, are merely backward, and how many are constitutionally defective. Second, to help determine what part the mental defects have played in the moral delinquency. Third, to find out, if we can, some of the reasons why many are subnormal mentally, and incidentally open the way for suggestions leading to prevention and cure. It was feared that some of these boys might prove to be indifferent or purposely misleading in their answers, and thus interfere with the validity of the tests; but we have been very much gratified with the spirit shown by the children in responding to the various tests put to them. The special teacher who has done most of the work, under my direction, has taken infinite pains and displayed a great deal of patience, encouraging them without helping them in their answers, and carefully refrainning from correcting any of their errors.

The smaller boys were tested first, so as to prevent their pestering the others, although I do not see how they could very well have done so, since they were all given the impression that their answers were correct, whether they were or not. As regards the value of the Binet-Simon tests, we must have some standard, and undoubtedly these tests are the best yet devised; Goddard, after examining 2,000

*Read before the Bronx Borough Medical Society, February 12, 1913.
school children, finds them amazingly accurate. Judging from the results obtained in this series of tests, I believe that if properly made they will give one a fairly correct mental age in any average class of children. For those of you who are not familiar with the Binet-Simon system, I may explain that it consists of a series of questions and tests arranged in groups of five: one group for each age from three to thirteen years, increasing in difficulty as we go along from the simplest questions and memory tests up to puzzling problems and comparative definitions in the thirteen year group. This group seems to me to be too difficult, and there is too great a gap between it and the twelve year tests. One or two intervening groups less severe, making the thirteen year questions an adult test, as has been suggested elsewhere, would be more satisfactory. As it stands now, boys of from sixteen to nineteen years are at a disadvantage; if they pass the twelve year group successfully and fall on the thirteen year, they must fall from three to six years below normal, which is often an injustice. Some of the questions appear at first a little ambiguous, affording a rather wide latitude in the answers, for example: What would you do if you were going to catch a train and missed it? It is obviously the intention for the child to elect to do something sensible under the circumstances. Another question of this kind is, What would you do before taking part in some important undertaking? One observer criticises this question because some of his adult friends gave the following answers: "Take a bath," and Transfer your property to your wife." It must be borne in mind that these tests were made for children, not for adults. I doubt if it would be possible to formulate any series of tests which would satisfactorily measure the adult. Children's minds are simple and the adults' too complex and specialized.

I have not placed much dependence on the cutting paper and reversed triangle tests; few of my friends or family have been able to answer them correctly, and good marks for the definitions contained in the thirteen year group have been deemed sufficient to place the boy in the normal class. Of the 150 normals and plus normals, thirty-five failed absolutely on the cutting paper test, and sixty-three on the reversed triangle problem; sixty did well enough to pass both these. Any series of tests for measuring native mental ability should depend as little as possible on educational advantages; this is aimed at in the Binet-Simon system, but it is obviously impossible to entirely eliminate such questions. Arithmetic is pretty well excluded, and should be, since it is a well known fact that quickness in arithmetic depends a good deal upon a certain genius for figures exhibited sometimes by persons otherwise subnormal mentally; still, the first test usually put to a suspected child either by a layman or untrained professional man is a question from the multiplication table or a request to count or change money. It must be remembered that these boys with whom we are dealing are many of them different from the average youth of normal and healthy tendencies; their mental machinery does not operate in quite the same way, owing to lack of education, vicious environment, and bad or negative home training; the education they have received has been that of the street and street gang. As a class they are skilled in craft and deceit, the natural result of more or less continuous efforts to evade detection and punishment for playing hookey and many other more serious offenses against the law. This often passes for mental ability, when it is only a sort of surface cleverness resulting from the sharpening of a few faculties that have been concerned in the exercise of that strongest law of nature, self preservation. In arithmetic, more especially mental arithmetic, they compare favorably with average boys who have enjoyed as little schooling as they have. It may readily be seen why this is so, since many of them have been making a more or less precarious living in the streets selling newspapers, blacking boots and patronizing pawn shops; all of which have tended to sharpen their figuring capacity in a marked degree. In geography and in matters pertaining to time and location many of them are wofully deficient. In this connection it is interesting to note that over fifty failed to name the months of the year correctly, a question belonging to the ten year group. Anything of purely literary value has no place in their mental curriculum. Conditions under which most of these boys have been living have narrowed their mental horizon, and this, combined with a minimum of school education, renders them rather difficult subjects for any satisfactory mental test. Then, again, most of them are possessed of a very limited vocabulary containing specimens of slang incomprehensible to the average man, just as many rather common English words are beyond their comprehension. Eighty-nine were of foreign birth who came to this country having learned no English and little else, and 101 born of foreign parents who have lived all of their lives on the lower East Side, where little English is spoken. For this reason it has been necessary to consume considerable time and patience in making these tests. We must also remember that we are dealing with a greater or less degree of perversion in many of these boys; their environment and habits of life have warped their mental outlook and distorted their sense of proportion, and as we go down in the scale we find many without ideals or any sense of humor more subtle than that supplied by the Sunday comic supplement. This description by no means applies to our boys as a whole; many of them are bright, capable youngsters, more sinned against than sinning, who make good in after years. The physical condition of these children is quite up to the average; I have examined a great many of them and they have few physical abnormalities, stigma of degeneracy, or signs of congenital lues. They resist attacks of acute illness as well if not better than other children of the same age. Twenty-six, or six per cent., are the subject of nocturnal enuresis, or flaters, as they are called; which is a larger proportion than we would be likely to find among the same number of boys of average mentality. Of the 400 examined, there were twenty-eight foreign born Italians and thirty-eight born in this country of Italian parents; thirty-eight foreign born Hebrews, eighty-eight native born Hebrews of foreign born parents; forty-six Irish, two of them born
in Ireland; forty Americans, twenty-five Germans, all born here; sixty-one negroes; and the remainder is made up of eight miscellaneous nationalities.

The accompanying charts give the tabulated results. No. 1 is diagrammatic, and shows in blocks the relative number of norms and subnorms of different mental ages. In chart No. 2 the Arabic figures represent the mental and the Roman numerals the physical or chronological age. It will thus be seen that out of the 400, nine tested one year above normal, 141 at normal, ten, one year below; twenty, two years below; forty-four, three years below; forty-nine, four years below; fifty, five years below; thirty-three, six years below; twenty, seven years below; ten, eight years below:

Chart No. 3.

Chart No. 3 shows the results obtained in the different nationalities as follows: Eighty-nine were foreign born; of these, two showed one year above normal, seventeen normal, and seventy below normal, or seventy-eight per cent. subnormal. Many of these were very deficient in English and had received little or no education. There were 101 American born of foreign parents; of these, three were above normal, seventy-three normal, and 115 below, or sixty per cent. subnormal. There were 109 Americans born of American parents, including negroes; four of these were above normal, forty-two normal, and sixty-three below; or fifty-eight per cent. subnormal. There were, in all, sixty-five Italians, thirty-two plus normal, fifteen normal, and forty-eight below, or seventy-three per cent. subnormal; 127 Hebrews—one plus normal, forty-three normal, and eighty-three below, or sixty-five per cent. subnormal; forty-six Irish—one plus normal, nineteen normal, and twenty-six below, or fifty-six per cent. subnormal; twenty-three Germans—eleven normal and twelve below, or fifty-two per cent. subnormal; thirty-nine Americans—two plus normal, fifteen normal, and twenty-two below, or fifty-six subnormal; seventy-one negroes—three above normal, twenty-seven normal, and forty-one below, or fifty-seven per cent. subnormal; and there were eight miscellaneous—three normal, and five below, or fifty-five per cent. subnormal.

In a general way it will be seen that the younger boys did relatively better than the older ones, and those of foreign birth, with seventy-eight per cent. deficient, pulled down the averages of the others. Much is being said and much written of late about mental defectives, and I believe that there is a good deal of conjecture in the popular mind as to what is meant by the word defective. The splendid work of Goddar, Whipple, Schlapp, and others in this country has done much to clarify the subject, and has called attention to a class of children whose special needs have hitherto been sadly neglected. Of the 250 boys who tested below normal in the House of Refuge, the majority in my opinion were free from any inherent mental defect; not more than twenty-five per cent. being constitutionally inferior. Most of these were of the moron type whose mental defects were not pronounced enough to fit them for admission to institutions for the feebleminded, but which were sufficient to handicap them seriously from a moral, economic, and eugenic standpoint. Three or four were low grade defectives having marks of degeneracy, such as facial asymmetry, microcephalus, and the like, and general mental and moral inefficiency. Two were victims of epilepsy. Professor Gesell, of Yale, estimates that twenty-five per cent. of all inmates of criminal institutions are constitutional inferiors. Any discussion of these low grade defectives does not lie within the scope of this paper; we are more concerned with those belonging to the higher grades, and they form a most interesting group. About thirty-seven per cent. of those examined consist of what are commonly called backward children, slowed up boys who have been mentally arrested, whose mental development has failed to keep pace with the physical from a variety of causes, principally lack of education or any sort of mental training. I have been much surprised while going over the records to observe how little schooling many of these boys have had; some had never been to school more than a month or two, and a good many less than one year in their whole lives. This would indicate considerable laxity in the enforcement of
our truancy laws among the children of the lower classes. Cruel treatment, neglect, vicious habits, and environment play an important part in checking the mental growth in many of these children. Any one familiar with the history of some of these boys can readily understand why they are mentally dull and morally perverse. Many of these subnorms could be brought up to standard by diligent treatment, if applied early enough; it is quite possible that under proper mental training and occupational teaching their mental age would catch up with the physical before maturity. It is important that mental defectives should be recognized and treated as such in our public schools, but it is even more important that the defectives in our institutions and reformatories should receive our attention, and particularly those among the street urchins who continually play truant from school, for it is this class of children who in the absence of home training, and living in a degrading environment, become unfit in later years. Vast numbers of defective children come into this country through Ellis Island every year. There ought to be more stringent laws or a more rigid enforcement of the existing ones, to prevent the influx of these undesirables. In order to give these boys the most intelligent help it is important that we should study their mental needs both as a whole and individually; we must realize that, generally speaking, there is something wrong with their mental as well as their moral equipment. Mental and moral weakness are closely associated, and proper education before these children reach the stage of incorrigibility would save many of them from becoming inmates of our reformatory schools for delinquents. Occupational schools are being started among the children of the lower East Side, and this is a step in the right direction; turning their minds and hands toward something useful and away from the education of the street, which leads to lawlessness and crime. We must try to change the juvenile delinquent’s viewpoints, and straighten out his sense of proportion, so that he will realize how much more sensible it is to work and get paid for it, and be independent, than it is to work for the State at menial tasks for nothing, plus the deprivation of his liberty. Abstract moral teaching is of little use; elevating the mental standard raises the moral with it, and will accomplish reformation from which there will be no backsliding.

423 East 130th Street.

HIGH PRESSURE DISEASE.

By Stewart R. Roberts, S. M., M. D.,
Atlanta, Ga.,
Professor of Medicine, Atlanta Medical College.

Associated disease of the arteries, kidneys, and heart is the pilot that puts out to sea with more adults than any other. The functional basis of cardiovascular renal disease is high blood pressure; the anatomical basis is sclerosis of the arterioles and arteries. It is a circulatory disease involving the vascular system of which the kidney is a part. Functionally the kidney is mainly a secreting gland, but structurally chiefly a vascular organ.

Association and progression are the two fundamental ideas involved in high pressure vascular renal disease. While it is true that at the time of examination a patient may have sclerosis without high pressure, at some time in his life he probably has had high pressure. High blood pressure is the force that holds the arteries, kidneys, and heart in this pathological association, though each of the three anatomical factors progresses along morbid avenues peculiar to itself alone. For example, in this associated progression the arteries may pass through the stages of increased pressure, sclerosis, calcification, weakness, and rupture; the kidney, through sclerosis of the arterioles, fibrosis, and renal atrophy; the heart, through increased work, high pressure hypertrophy (Reisman), valvular incompetency, myocardial degeneration, and dilatation.

This association of high pressure, arteriosclerosis, renal fibrosis, cardiac hypertrophy, with progression toward apoplexy, uremia, or cardiac failure, is a disease without a name. It is more than pressure and more than sclerosis. It is a disease, a varying morbid entity of many factors, but a morbid entity always. The name high pressure disease seems to me simple, exact, and inclusive. High pressure disease is capable of division into periods, especially when it is realized that the disease is a progression and not a stasis, an evolutionary degenerative process of increasing mechanical strain and tissue changes. There are three general periods corresponding in order both as to severity and to time: 1. Period of high pressure with or without sclerosis. 2. Period of strain, as evinced by vascular, renal, cardiac, nervous, respiratory, digestive, and weight symptoms. 3. Period of failure; a, vascular failure as apoplexy; b, cardiac failure, as myocardial disease and dilatation; c, renal failure, as uremic headache, stupor, and coma.

The damage is rarely equally distributed, and the clinical symptoms arise first from that organ where the process has been most rapid and the damage the greatest. Apoplexy may occur before there are any cardiac symptoms, though hypertrophy and a ringing aortic signify that the heart is an accomplice. Uremic headache, increasing stupor, frequent vomiting, increased quantities of urine of low weight, albumin in traces, and casts in abundance are the renal symptoms that signify that the kidneys have suffered most in the associated progress, though the vessels are hardly palpable, and the patient has had no cardiac symptoms. Increased amount of urine of low weight without albumin or casts, but with high blood pressure signifies increased renal tension, and usually there is low phthalein output. There may be high pressure without initial sclerosis or renal involvement, though perhaps it would be better to say without ascertainable cardiac, renal, or vascular changes. Continued high pressure will later involve the renal vascular system, by leading to arteriosclerosis and its evolution. The following cases illustrate different phases and symptoms of high pressure disease, and the progression to apoplexy, cardiac failure, and uremic states. The work of the heart can roughly be calculated by the formula: Pulse rate by systolic blood pressure equals work of heart. A normal rate of 72 with a normal pressure of 130 mm., under this formula (pulse rate
X systolic blood pressure work of heart) is 9,000 units. In each case of high pressure disease it is well to calculate this work before and after treatment, as it affords a double check on the condition of the patient and the results of treatment. These figures are given in each case. After the patient returns to his usual work the figure rises. The object of treatment is to keep it well within safety limits.

Case I. High pressure cardiac hypertrophy with congestive failure. 

H. P. R. (now forty years old) weighed 190 pounds, had worked uneaingly for large stakes for four years. He had noticed occasional throbbing headache and ringing in left ear. One morning he awoke with paralysis of entire left face. On examination, arteries palpitating; pulses hasty; apex beating was diminished; systolic hypertension. The diagnosis was arteriosclerosis; accentuated aortic hypertension; accentuated aortic. Blood pressure S. P. 225, D. P. 140, P. P. 85; urine low weight, negative, except for indican and increased twenty-four hour amount. On a régime of less work, more relaxation, purgation, and aconite, improvement in two months, with pressure reduced to 160 mm.; pulse 80. Before treatment, work of heart 20,000; after, 12,000. Normal, 9,000. No loss in weight.

Case II. High pressure arteriosclerosis with threatened cardiac failure. — A painting contractor, fifty-eight years of age. After a day's work became emotional, cried, complained of a jumping heart, and feared death. After crying he was better. He had had similar attacks before, attended to in the usual manner for a week. These were probably vascular crises. Had complained of occipital neuralgia and throbbing head for four years. Pulse 76, with premature contraction every ten to twenty beats. Blood pressure S. P. 250, D. P. 150, P. P. 85. Cardiac hypertrophy; accentuated aortic. Blood pressure S. P. 225, D. P. 140, P. P. 85; urine low weight, negative, except for a few casts and indican; renal test thirty-five per cent. Dyspnea on rapid walking; heart enlarged; marked mitral; lesser but accentuated aortic; arteries palpable, hard, and tortuous. Admitted to hospital; confined to bed for two weeks; bleeding, purgation, restricted diet, and aconite. Pulse was 64; blood pressure S. P. 172, D. P. 114, P. P. 58. Work of heart 17,000 before treatment; 11,000 after. Normal, 9,000. Lost five pounds.

Case III. High pressure kidney, uremic symptoms, transient hemiplegia. — A broker of sixty-two years, weight 205 pounds, had noticed for weeks a peculiar taste and breath, dizziness, sleepiness much of the time, and increasing nycturia. In February, one day after dinner, there suddenly developed a numbness and tingling over left side, from toes to hip and fingers to shoulder, with numbness, weakness, and a feeling of stupor and fulness in head. On examination, pulse 80, full and bounding. Blood pressure S. P. 220, D. P. 160, P. P. 90. Cardiac hypertrophy; a soft mitral, alternating with a blowing aortic. Heart six and one half inches transversely. General puffiness, uremic breath, dyspnea, nycturia from two to three hours after meals; indurated kidneys in many casts. Patient confined to bed for one month, bleeding, restricted diet, purging, and aconite. Pulse was 68; blood pressure S. P. 170, D. P. 140, P. P. 30; nycturia, once or twice. Before treatment, work of heart 21,000; after, 11,000. Normal, 9,000. Lost ten pounds.

High pressure and isolated arteriosclerosis are the first clinical symptoms of associated high pressure disease. Constriction of the arterioles may occur first in the kidney, in the splanchic area, in the aorta or its branches above the diaphragm, or in the retina. The palpable arteries may be normal, and the vascular sclerosis exist in the hidden parts. Distinction must be made between high blood pressure without sclerosis, high blood pressure with sclerosis, and sclerosis without high pressure, as in the old and in the infirm. High pressure, palpable radials and temporals, cardiac hypertrophy, and accentuated aortic are the four signs of arteriosclerosis: but high pressure may long precede these signs. Arteriosclerosis is not a disease that lives unto itself, but is a systemic morbid process with the arterioles as the chief criminal, and the kidneys and heart as accessories after the fact. The chief resistance to blood flow is in the arterioles, and there the process starts.

The high pressure may be initial: 1. The result of worry and mental strain, because in such times more adrenaline is poured into the blood, and thus high pressure is caused before sclerosis begins. 2. The result of overeating, with the spasmodic, periodic overworking of the vast splanchic area, with overwork of the heart and renal arterioles. 3. The result of a systemic circulatory toxin arising from a, intestinal putrefaction; b, endogenous tissue poisons: c, toxins from infection, as syphilis, typhoid fever, malaria, influenza. Here the later sclerosis is simple hypertrophy of the vessel wall due to its increased work.

The arteriosclerosis may be initial, due to arteritis, endarteritis, syphilis, physical work, toxins, overeating, mental strain, bad tubing, and age. Senile arteriosclerosis is the vascular disease of time. The high pressure is therefore necessary to force the blood through the arterioles, where the resistance is always greatest, and not in the capillary bed as was formerly taught. This is compensatory high pressure. The danger element is the pressure, not the sclerosis: the bore of the vessel and not its wall. The bore may be decreased by vascular spasm without sclerosis, or by actual sclerosis. The greater the decrease in the bore of the vessels, whether from spasm or sclerosis, the higher the pressure: the greater the renal atrophy and the cardiac hypertrophy. The danger is vessel rupture. Apoplexy is a vascular disease damaging and compressing nerve tissue, and it is surprising how many cases of high pressure disease are terminated by apoplexy.

Our ideas of interstitial nephritis need revision. I doubt if there is such a thing as primary nephritis. There is acute tubular and acute glomerulotubular, and chronic tubular nephritis. These are inflammations of the kidney. There is increasing evidence in favor of the degeneration, atrophy, and fibrosis of the kidney; which in the majority of cases is the result of sclerosis of the renal arterioles. This is a "renal atrophy of circulatory origin" (Barker), a degeneration, but not an inflammation: an inactivity atrophy, but not a nephritis. Of course, there is that large group of secondary contracted kidneys, with a process of fibrosis, the result of acute tubular and chronic tubular nephritis. This is a scar kidney, a renal cicatrix, a healing of a tubular nephritis. The renal arteriosclerosis is but a part of the systemic arteriosclerosis: the damage is to the glomeruli and causes the late degeneration of great numbers, with atrophy of their connecting tubules. Arteriosclerotic renal atrophy gives, therefore, increased quantity of urine of low weight and casts, but little albumin: whereas a true nephritis gives a decreased quantity of urine of heavy weight, casts, and much albumin. In nephritis there is an inflammation of the kidney: in renal arteriosclerosis there is a degeneration, and the process is systemic and vascular, and not localized and inflammatory. We have regarded the kidney so long as a compound tubular gland that becomes either acutely or chronically inflamed that we need to remember that it is also a vascular organ that may yield to arterioscle-
rosis and its accompanying degenerations and atrophies. Instead of the term interstitial nephritis, I prefer the high pressure kidney, or the arteriosclerotic kidney, of which there are probably two types: 1. Renal sclerosis primary, and secondary systemic high pressure sclerosis. 2. Systemic high pressure primary, and renal sclerosis secondary, to this general vascular degeneration. Renal arteriosclerosis raises the pressure and involves the heart; systemic arteriosclerosis raises the pressure and involves the kidney in its vascular parts. The difference is in the starting point, not in the process.

Circulatory disturbance anywhere puts more work on the heart. High pressure causes heart strain. As sclerosis develops, the strain increases, high pressure hypertrophy results, and the cardiac reserve decreases. Moreover, in high pressure disease there is none too much reserve to draw upon, and hypertrophy is all the more rapid. In addition to the muscular overwork, there comes the valvular strain both upon the aortic valve that stands the diastolic strain, and the mitral valve that stands the systolic strain. The accentuated aortic, the accentuation with the aortic leak, premature contractions, arrhythmia, anginal pains, then these with the basic systolic murmur, then the heaving impulse and the mushy mitral, and dilatation is at hand. The strain of the mitral is to the strain of the aortic valve as the blow of the bat is to the lesser force with which the fly ball drops into the fielder's glove. Dropisy does not begin until the myocardium fails. As distinguished from primary organic disease, the damage to the heart in high pressure disease results from conditions outside the heart; in the one the heart is primarily diseased, in the other the heart is primarily overworked, and later diseased when the pull uphill has been too long or too heavy. The vis a tergo surrenders in time to the vis a fronte, and high pressure cardiac failure begins. The mechanical conditions of high pressure that in the beginning cause hypertrophy are able in time to cause dilatation. The condition of the myocardium, the extent of its hypertrophy, the position of the apex beat, as determined by palpation and percussion, are relatively more important for treatment and prognosis than auscultation, valvular accents, and murmurs. Area, rather than murmur, size rather than sound, is to be considered. Only when the vessels and kidneys withstand the strain does the heart thus progress to ultimate failure. Very slight hypertrophy may exist, and yet death come from apoplexy or uremia.

TREATMENT.

The treatment of high pressure disease is mainly directed toward a reduction of the high pressure if seen in the first or second period. If seen in the period of failure the treatment is directed to that organ evincing the most serious symptoms, and later to the high pressure cause. The disease is one of development: the pressure rose gradually, and the treatment must permit the pressure to fall gradually. It will rarely return to normal, certainly not at all if sclerosis has begun or the period of strain has come. The descent must be gradual to a permanent plateau above the normal. The following outline affords a basis for treatment.

1. The patient must relax into a state of repose of body and mind. Rest in bed from two weeks to a month aids one to realize that the "break" has come in his physical and mental activity, and that the tense exertion, anxiety, and worry must yield to more rest, calmness, and poise. Physically the bed is a vasodilator of no mean power.

2. Bleeding in selected cases, after a few days' rest in bed. Pressure should be taken before and after bleeding. A fall of not over fifty mm. is safe. The fall of the pressure in millimetres is the guide to the amount of blood to be withdrawn. The patient should remain in bed a week after the operation.

3. Mild catharsis frequently repeated, and not fierce catharsis, infrequently repeated.

4. In the puffy or plethoric patients a loss of from five to twenty pounds is desirable, and the diet is graded accordingly. Later a low grade egg, milk, cereal, and vegetable diet, decreased liquid and salt intake; with never a stuffy meal.

5. The tincture of aconite, in doses of from three to eight drops, once to thrice daily, is the only drug I know that will with safety and certainty lower blood pressure, and, what is more important, keep it lowered. The official tincture is now a ten per cent. solution, not the former strong and dangerous thirty-five per cent. one. It stimulates the vagus, and thus slows and steadies a straining and overworked heart. It slows the blood current and lowers the blood pressure. It can be given for months to a patient without danger. It relieves the throbbing head and ringing ear of the high pressure patient, produces a sense of calmness, and aids sleep. I have never had any results from the nitrates, and but little from the iodides (except in syphilitic high pressure disease) in this warm southern climate, where the arterioles and capillaries are already climatically dilated. It may be different with Sir Lauder Brunton in cold England. Aconite steadies the heart, lessens its load, dilates the arterioles, flushes the kidneys with a physiological tension, calms the whole circulatory system, permanently and with safety. I have used it in the old and infirm, and in the young and strong.

6. Sodium chloride (ice cream salt) and calcium chloride baths. Later the Nauheim baths at home in certain cases.

CANDLER BUILDING.

ANTRAL EMPYEMA, WITH THE PRESENTATION OF AN EFFICIENT CONSERVATIVE OPERATION FOR ITS CURE.*

By H. C. Masland, M. D.,

The title of my paper indicates that the treatment to be outlined is adapted to those conditions where we have diagnosed pus in the maxillary sinus. It is not necessary in the primary stages of acute sinusitis. While many of these cases go on to the formation of pus, it is my experience that

*Read before the Philadelphia Clinical Association, April 21, 1913.
topical and general medical treatment, early and vigorously pursued, will effect a cure.

Practically all cases of suppurrative sinusitis are of dental or nasal origin. Naturally, one should strive to determine the origin in each case, and where an offending tooth is the source, it should receive proper dental treatment. This may be sufficient, but where the sinus has undergone inflammatory change some thorough method of drainage will be required. The older method of puncturing the antrum through the alveolar process is falling into deserved disrepute. The great likelihood of contamination through the mouth and the difficulty in cleaning and keeping the tract open are sufficient to condemn this procedure. In the cases of nasal origin Ballenger lays much stress on obstruction and deficiency of ventilation, due to anatomical conditions in the so called “vicious circle.” This, with the presence of the exciting infection are, in his opinion, the causes of the majority of cases of suppurating sinusitis. This seems plausible, and yet we meet cases where the examination reveals a reasonable degree of separation of the middle turbinate from the septum and from the underlying outer wall of the nasal chamber. It is my belief that many of these cases do not depend so much on an anatomical abnormality, as upon a neglected or carelessly treated case of acute sinusitis, following a neglected chronic rhinitis. An infection once planted in these cavities, with the means of drainage through the natural opening so poorly adapted to the purpose, the condition tends to last indefinitely. Former beliefs as to the frequency of bone necrosis in these cases is now known to be erroneous. Bone necrosis is not frequent, and when it is present it is my practice to give specific treatment a thorough trial, as many such cases are syphilitic in origin. The mucous membrane is not hopelessy diseased. It will regain almost if not quite a normal tone if drainage is complete and the constant irritation of retained pus is removed.

In considering the treatment of maxillary sinusitis, a knowledge of the anatomical relation of the parts is important. At birth, according to Leidy, the antrum is of considerable size, making its appearance at the middle of fetal life. It lies in the superior maxilla, above the alveolar process of the three molar teeth. Its base presents internally, forming a part of the outer wall of the nasal chamber. The natural opening of the antrum is in the upper part of the cavity and drains into the middle meatus. The location of this opening high in the antrum, however well it may be adapted to normal physiological function, is incapable of draining abnormal pathological fluids. The anterior wall of the antrum is generally convex in outline, and lies between the orbit and the alveolar process. The base and the anterior surface are the best adapted sites for operative interference.

I made passing mention of the operation through the alveolar process only to condemn it. It possesses no advantages not common to other operations, and does offer positive disadvantages. It is an absolute essential, admitting of no exception, that an operation, to give uniformly good results, must provide for good drainage and cleansing of the parts, that shall continue till nature has effected a return to health of the diseased tissue. This is the reason why puncture of the antral wall and attempted cleansing by the daily introduction of a cannula by the physician fails in all save the mildest of cases. The patient will not appear for daily treatment, and the opening closes before the cure can be accomplished.

The Vail, Denker, Caldwell-Luc, and many other operations all provide for more or less extenotive removal of the anterior or internal wall of the antrum, or both, leaving so large a resultant opening for drainage that Nature is incapable of readily closing it. These are radical operations which in a very large proportion of cases will effect a cure. The objections are that they incapacitate for some days; they are mutilating; they remove a large portion of the inferior turbinate and the external wall of the nasal chamber, leaving considerable cicatrical tissue, which is always objectionable; they practically convert the antral cavity into a part of the nasal chamber. It is evident that various physiological functions are, by the above methods, perverted or destroyed. Further, these operations, while they drain well, are inefficient as regards the cleansing that is so essential, requiring a degree of zeal and intelligence on the part of patients which many of them do not possess. Presuming a short stay in the hospital, the majority of them will not return to the physician’s office for daily treatment. Should they have a Krause cannula or other instrument for douching the antrum at home, they are just as likely to introduce the instrument into some other part of the nasal chamber. This naturally delays the recovery. It is our business to regard the shortcomings of the patients and insure the best results with the least destruction of tissue and disturbance of function.

Some seven or eight years ago I resolved to work along the lines indicated by Freeman in the use of his straight self retaining cannula. I punctured the antrum in the inferior meatus, and introduced a Freeman cannula. Within a few hours the chafing and pressure upon the septum gave so much distress that the immediate removal of the cannula was imperative. I then had made a curved cannula, which with some minor modifications, was like the one here shown. (Fig. 1.) My patient made a prompt and perfect recovery, though for years she had had a free purulent discharge, foul odor, and other typical symptoms of antral abscess. Two years afterward this patient, a diabetic case, came to my office perfectly well and bringing a thank offering of the products of the farm. My subsequent cases have given uniformly satisfactory results.

In describing this operation there are certain features I wish to make emphatic. It is not a mere puncture operation, with a curved trocar going through the thin wall of the inferior meatus. I use a straight trocar with a drill shaped point. The hole is cut, not punctured, in the inferior meatus on the floor of the nose, the aim being to reach as near as possible the bottom of the antral cavity. Drainage must be from the bottom of the wall. It is almost impossible to open the thicker bone process at this
site with a curved trocar. If by chance it should give way there is grave danger of the uncontrolled force carrying the point into the opposite wall of the antrum. A curved trocar is more prone to slip and lacerate the mucous membrane. The straight trocar is introduced till its point is at the site for operation. The handle is then tilted sharply to the opposite side, and with moderate pressure and steady rotation the instrument is made to cut its way into the antrum. When through, the trocar is withdrawn from its cannula, and the pus will make its appearance. In the majority of cases I find it necessary to snip off just enough of the inferior turbinate to allow ready access to the site of operation.

The self retaining cannula has a collar at its inner end and one also beyond the curve, of the same diameter as the trocar cannula. These prevent the cannula from either slipping into or coming out of the antral cavity. The nozzle end of the cannula is grasped by a hemostat and the instrument readily introduced. I tie a small silk loop just beyond the nozzle enlargement of the cannula. The nozzle aperture will admit the tip of an all rubber ear syringe. Standing before a mirror, the patient catches the silk loop with a hook or forceps to steady the cannula, and introduces the syringe tip and without any required skill flushes and cleanses the antrum. When properly placed, the cannula rests comfortably on the floor of the nose just within the vestibule. It is not noticeable to ordinary inspection, but tilting the tip of the nose brings it into view. The patient considers it no hardship to douche the antrum once daily. He comes to my office once or twice weekly for inspection and the correction of any incidental inconveniences that may arise, and for such additional topical applications as conditions indicate. The cannula is retained in situ till the abnormal secretion has disappeared, and the patient looks and feels well. A month’s time in my experience has effected this result in very severe cases.

As regard medicines used, I prefer a sodium bicarbonate solution for home flushing; in my office a weak liquor cresolis compositus solution, and, occasionally, applications of argyrol or weak zinc sulphate solutions.

I have confined this paper to the consideration of the treatment of pus in the antrum. It is well known that old cases of maxillary sinusitis are frequently associated with involvement of the anterior ethmoidal and even more posterior cells. One of my recent cases showed involvement of the ethmoidal cells, in addition to the antral trouble, and yet the discharge eventually disappeared. The great likelihood of communication between these cells and the gravitation of the pus to the lower antral cell offers a possible explanation and is worthy of consideration. I am convinced that the operation should be performed as a preliminary procedure in maxillary sinusitis when the anterior and posterior ethmoidal, or even the sphenoidal sinuses, are also implicated. The operation in the antrum may cure the deeper trouble. If it does not the nasal condition will be greatly improved and so give better promise of cure under subsequent radical interference. With the removal of the cannula the small opening usually closes. Thus a practically ideal cure is accomplished with no deformity and no disturbance of normal function.

2130 North Nineteenth Street.

FOOD FOR BABIES.*

By M. Alice Asserson, M. D., New York.

Never in the history of the world has there been so much done for babies as is now being done by all civilized nations, for most of these nations are alive to the fact that in the past there has been a needless sacrifice and that now something must be done in the way of “conservation of the babies.” For many years France has had to face the situation of a decreasing birth rate. Babies are at a premium there and must be saved at any cost. There are consequently in France many schemes on foot for the reduction of infant mortality. In connection with many of the large manufacturing plants and municipal workshops where women are employed, a crêche, or day nursery, is established. The babies are cared for by nurses and the mothers are excused from their work at definite and regular hours in order to nurse their infants, some of the employers even going so far as to deposit 100 francs in the bank for any baby which is breast fed up to the weaning age. In some of the German cities another plan is adopted. If a working mother is able to prove to the government that she will nurse her baby and give it the proper care at home, she is paid a sufficient wage to make it worth her while to stay at home during the breast feeding period. These methods show us that there is a keen realization in these two countries not only of the importance of caring for the babies, but of caring for them as Nature intended them to be cared for. In this conservation of infant life the object is not only to save the babies, but to give them every opportunity to become useful, healthy individuals, with normal minds and vigorous bodies, to fit them for the struggle for existence. The effects of bad feeding and bad food may last through life, giving the individual a handicap which is an injustice to him. When one considers that the largest part of infant mortality in the first year is due to disorders of nutrition one realizes the importance of this subject of food for babies.

The normal food of the baby in its first year is breast milk, and any other food is abnormal. A large proportion of the babies of to-day are not breast fed. One hears many reasons and theories to account for this state of affairs. Some are pessimistic and consider that with the wear and tear of modern life the normal function of the breast is rapidly disappearing. While others are more optimistic and consider that, although breast feeding is now at a low ebb, in the course of one or two more generations conditions will improve, owing to the fact that young people are more athletic and that more attention is paid to general hygiene than

*Prepared at the request of the Public Health Education Committee of the Medical Society of the County of New York and read under its auspices at the New York Academy of Medicine, March 5, 1913.
formerly. Certainly it seems as if these improved conditions should give us healthy mothers, with normal functions. However, to-day, it is true, that the bottle fed babies are far too numerous. It is rare to find a woman who will not nurse her baby, but it is not rare to find one who cannot. This is a condition prevailing among the wealthy classes, as well as among the poor. Among the latter, however, there are many who must forego this maternal duty in order to support themselves and their families. The responsibility of parents in the matter of rearing children is a tremendous one, as heredity and environment play such important roles in the development, mentally and physically, of the child. For lack of time the question of environment is the only one we shall be able to consider, as this is the one which concerns us most in the child's physical development.

The human body has its starting point in a single cell, which after impregnation divides and subdivides until the human form results. The vitality of the organism depends upon the vitality of each individual cell, and as these receive their nourishment from the mother's blood before birth one realizes the important part the health of the mother must play in the future welfare of the child. Consequently, when a woman becomes pregnant her first thought must be directed toward her own health and well being. There are many important factors in her daily life which should be considered. Her disposition should be calm, thoughtful, and placid, and her diet must be sufficient in quantity and varied to include meat, fish, vegetables, cereals, and fruits. Constipation is often a very obstinate condition in pregnancy. As there are waste products of both the mother and the fetus to be disposed of, one may readily understand the importance of at least one daily evacuation of the bowels. If this cannot be obtained by laxative foods drugs must be resorted to, under the direction of a physician. Frequent warm baths and six or eight glasses of water daily will keep the skin and kidneys active, while moderate exercise in the open air will help all the functions of the body. Nursing will be facilitated if some attention is paid to the nipples during pregnancy. It is well to begin a few weeks before the expected confinement to bathe them with a boric acid solution and to make applications of some astrigent lubricant. If they are inclined to be flat or depressed they should be drawn out once or twice daily.

Stanley Hall aptly says: “A man is what he eats and what he does with it through all the intricate formulae of physiological chemistry.” I might add that this is particularly true in the first two years of a child's life, when the question of nutrition is one of extreme importance. Mistakes at this time are serious. In the adult only enough food is needed to repair waste, while in the child enough is needed to repair waste and build up new tissue also, as there is a tremendous growth in these first two years of the skeleton, visceral organs, nervous system, and brain, the latter organ doubling in weight and increasing in complexity. Before birth the baby is nourished by the mother's blood; after birth by milk secreted in the mother's breast—the ideal food for the baby.

The composition of this food is protein, fat, sugar, mineral salts, and water in definite proportions, subject to slight variations—the protein in the proportion of 1.5 per cent., the fat four per cent., sugar seven per cent., mineral salts two per cent., water 87.2 per cent. The protein is in suspension, the fat in the form of minute globules, in a state of emulsion, and the sugar in solution. Practically all food has the same composition, the main difference being one of form and proportions.

As the baby grows and its digestive organs develop, the mother's milk changes to meet the demands and requirements of this growth, thus preparing the way for the more solid food of the second year. At birth the digestive organs of the infant differ anatomically and physiologically from those of the adult, the baby having no teeth and its gastric juice differing in strength from the adult gastric secretion.

After the food has entered the stomach it must be changed chemically to be of use. The liquid milk is converted by the action of the gastric juice into a semisolid mass of finely divided curds, the protein being broken down into albumoses and peptones. The contents of the stomach then pass through the lower opening or pylorus into the small intestine, where still greater changes take place by the digestion of the fat and the sugar, the fat being emulsified and the sugar broken down into dextrose and levulose. After the food has been digested the products of digestion pass into the blood, where they are carried by means of the blood vessels to all the cells of the body. These cells, having a selective power, take up the substances required for their individual and peculiar needs. The fat and sugar over and above what the cells need are stored up in the body, as a reserve fund for use in case of illness, the sugar being stored in the liver as glycogen and the fat under the skin and about the organs as fat, while the protein excess is excreted in the urine. Nature has given each food element certain definite work to do, the fat and sugar supplying heat and furnishing living force, the protein building up growing tissue and repairing the work of the body cells, and water supplying a medium for the solution and suspension of the food elements.

After the birth of the baby the mother should have a rest of six or eight hours, when the baby may be put to the breast. The first secretion of the breast is a substance called colostrum, which is digested with ease, as it forms no curds, its protein is soluble and its sugar dextrose. It serves its purpose as a laxative and prepares the digestive tract for its regular food. About the third day milk is secreted and from this time until the end of the sixth or eighth week regular, two or two and a half hour intervals of nursing should be established, with one or two night feedings. After the eighth week, three hour nursing intervals, with no night feeding, may be established, to be continued until the end of the first year. Boiled water without sugar should be given three or four times during the day, between the nursing periods. Regularity of feeding is a stumbling block with many mothers, for the reason that babies sleep a great deal in early life and few mothers realize the importance of
waking them at their regular nursing periods. If this plan is adopted, the baby soon learns to regulate himself, and will awaken with clocklike regularity for his meals.

Irregular nursing is one of the most frequent causes of indigestion in the breast fed infant. If the interval is too short the remains of the previous meal may still be present in the stomach; if it is too long the baby nurses greedily and overloads the stomach. There are also changes in the milk which are harmful to the child's digestion. If the interval is too short the milk is reduced in quantity and the fat increased; resulting in vomiting or diarrhea. If, on the other hand, the interval is too long, the milk is increased in quantity and decreased in solids, with the result that the baby is not properly nourished. When regularity is observed the food has about the same composition and is digested with comfort. The majority of breast fed babies thrive when managed with intelligence. They are apt to fall asleep while nursing, and are happy and contented. The muscles are firm, the skin clear, and the eyes bright. They have two or three yellow stools daily and increase in weight from four to six ounces a week in the first six months, and after that, from two to four ounces a week. A normal baby usually doubles his weight in six months and triples it in one year. If there is not sufficient milk, the baby nurses for a longer period than twenty minutes (usually from one half to three quarters of an hour), cries when taken from the breast or sometimes cries before his next feeding is due. If the condition is not recognized the baby loses weight, sleeps poorly, and becomes listless, pale, and anemic.

It is not always smooth sailing with a breast fed baby. If there is trouble, a physician should be consulted before making any change in the food, for often after modifying slight irregularities in the mother's daily life the trouble disappears. Sometimes in the first few weeks the breast milk disagrees with the baby; this may be due to one of many causes. If the mother has had a difficult labor it may take several weeks before she has overcome its effects sufficiently to produce normal milk, or from the inactive life during her convalescence certain elements in her milk, such as protein or fat, may be too abundant for the baby's digestion. These difficulties usually disappear as the mother assumes her regular duties and leads her usual life of activity. If, however, colic, vomiting, and other signs of indigestion persist the cause may be found in the mother's indiscretions. Colic with constipated stools may be an indication of too high a proportion of protein in the milk, possibly caused by too much meat, excessive tea drinking, or too little exercise on the part of the mother, with resulting constipation. When such irregularities are corrected these signs of indigestion may cease. Vomiting may be due to one of many causes. Regurgitation of food, or vomiting immediately after nursing, may be due to too frequent or too rapid nursing, with the ingestion of too much food, or it may be due to handling the baby too soon after his feeding; while the vomiting of sour smelling curdled milk a half hour or one hour after nursing may be an indication of excessive fat. This disturbing element may be reduced by a diet (for the mother) consisting principally of farinaceous or vegetable food, and by diluting the milk by giving the baby half an ounce or one ounce of boiled water or barley water immediately before nursing. When a mother understands how much depends upon the routine of her daily life and how easily the baby's food is disturbed by irregularities on her part, she will pay strict attention to every detail. Outdoor exercise must be taken every day and her diet should consist of a plentiful supply of digestible food, with enough variety to stimulate her appetite.

If there are certain foods which are not digested by her, whether they belong in the category of digestible foods or not, she should avoid them. Liquids, such as milk and cacao, should be taken between meals and at bedtime, if the milk supply is inclined to be scanty. Cornmeal gruel may be added with benefit to the diet. Tea and coffee are best taken in moderation, while beer and other alcoholic drinks are contraindicated. It should be the object of the family to protect the mother from all disturbing conditions; her life should be as carefree as possible, as her milk is often very much affected by worry, anxiety, grief, or anger; the child suffering in consequence from acute indigestion, vomiting, undigested stools, and, at times, high fever accompanied by convulsions.

Menstruation occurring during the nursing period is rarely disturbing enough to make it necessary to wean the baby. It may lessen the flow of milk and very occasionally may cause attacks of indigestion. These, if severe, may be avoided by feeding from the bottle for a day or two. If, however, pregnancy should intervene it is usual to wean the baby, as the milk then becomes poor in fat and the strain too great for the average woman. However, weaning may be deferred a few weeks if the pregnancy occur in midsummer and the baby is not strong. In cases of acute febrile disease of short duration the baby may be taken from the breast during the period of illness and nursed again upon the recovery of the mother. If the mother is the victim of chronic disease, such as tuberculosis, nephritis, or heart disease, nursing should be forbidden.

It is best to begin to wean the baby about the ninth or tenth month, as the stomach of the infant is then ready to digest stronger food and the mother's milk is beginning to lose its nutritive qualities. Many cases of rachitis, anemia, and malnutrition are due to prolonged nursing.

**ARTIFICIAL FEEDING.**

When it is not possible to give the baby his normal food we are forced to turn to artificial feeding. Here the responsibility of the mother toward her child is shifted somewhat to the physician's shoulders, for it is now the physician's duty to prescribe for the child, as a substitute, a food which will not only be retained and cause increase in weight, but one which will build up a healthy body with disease resisting tissues. It is conceded by the best authorities that fresh cow's milk is the best substitute, as it
has the same form and the same ingredients, though, unfortunately, also certain differences which must be overcome, if possible. The important problem presents itself of putting the milk of one species into the stomach of a being of different species with a different digestive apparatus. Cow's milk, with its high percentage of proteid, was intended for the rapidly growing calf, while mother's milk was intended for the delicate digestive apparatus of the baby, which Nature prepared for a long period of helplessness attended by a tremendous growth of brain and nervous system by the addition of a much larger proportion of lecithin than in cow's milk. Another important difference, but one which we can overcome in a measure is that of proportions; cow's milk having three times as much proteid and only a little more than one half as much sugar; though by dilution with water and cerebral water and the addition of sugar and cream the quantitative differences may be adjusted. This sounds very simple, but as a matter of fact it brings us up against another problem. The proteid of cow's milk is difficult for the baby to digest. It is the most important element in the food, as it is the tissue building one; yet in the early months we must dilute it below that of mother's milk before the baby can digest it. Consequently, the bottle fed baby in its early months may be receiving only one half as much of this important element as the breast fed baby of the same age. One has also to consider that mother's milk is always fresh and sterile, while cow's milk is usually twenty-four hours old, and more or less contaminated with dirt and germs.

This brings us to a very important factor in artificial feeding—cleanliness, which is the keynote to any successful feeding. It is absolutely essential that the milk should be clean. The stable, cows, milkers, and receptacles must be clean, and in order that the bacteria which are necessarily contained in the milk will have little chance to propagate, the milk must be quickly cooled to 40° F. and kept at a point below this temperature until ready for use. Other important essentials are: The milk must be fresh; must contain no preservative; it must not be skimmed; the cows supplying it must be healthy and the milk free from disease; mixed milk from a herd is preferable to one cow's milk, as this varies less from day to day. After the milk is received in the homes all the good may be undone by careless handling. The refrigerator must be immaculate, with milk compartments near the ice, so that the temperature of 40° F. or less may be maintained. The baby's milk should be grade A or certified milk, which answers to requirements of freshness and cleanliness, with a bacteria count of less than 30,000 to a cubic centimetre.

In selecting bottles, those of cylindrical shape are easier to keep clean than the flat shape. After use they should be rinsed in cold water and allowed to stand in borax water, and before they are used again they should be washed in hot soapsuds water and boiled for ten minutes. Nipples must be of such a shape that they may be easily turned inside out. Once a day this should be done, and they should then be scrubbed with soap and water. After use they should be washed first in cold water, then in hot, and then kept in borax water until needed.

The baby's food must be prepared carefully by an intelligent person, the hands and utensils scrupulously clean. In the early weeks many babies have less trouble in digesting milk with boiled water. The cereal dilutions which should be begun about the third month are advantageous in producing a flocculent curd and in giving a slight increase in the proteid element. In large cities, when certified milk cannot be obtained, it may be safe to pasteurize the milk, in order to destroy any pathogenic bacteria; in spite of the fact that the process renders the milk slightly more difficult to digest and causes constipation. The proprietary foods have their advantages and disadvantages. There are some babies who cannot digest the weakest preparations of cow's milk, and, here, by using temporarily some one of the proprietary foods, rich in sugar, the digestive disturbances may be overcome with the result that milk may be tolerated and digested later, thus tiding them over a difficulty. In traveling, the proprietary foods are of great service—they are easily carried and easily prepared and will keep for some days without ice; while the baby is saved from many changes in the milk. The chief disadvantage is that they do not contain the nutritive elements as they exist in breast milk, being usually deficient in fat and proteid and too rich in sugar and starch. If they are used without milk the results are bad, the baby becoming the victim of rhachitis or extreme malnutrition. There may be a steady gain in weight, due to the large amount of sugar digested, but the resistance to disease is very much lessened, owing to a deficiency in the most important food element, proteid.

For generations past mothers have had a dread and at times a superstitious fear of the "second summer." The second year marks a period of rapid growth and the appearance of most of the teeth, but the danger lies not so much in these two factors as in the carelessness of parents. There is a temptation now to give a taste of all varieties of food, thus spoiling the child's appetite for simple food. Many cases of chronic indigestion have their starting point at this time when a child is given a greater variety of food than he should have and allowed to eat between meals, to eat rapidly without proper mastication, and to indulge freely in sweets.

I feel that I have already taken a great deal of time, but my paper would scarcely be complete if I did not tell you even briefly what New York city is doing for food for babies. In the summer of 1911 the New York Milk Committee demonstrated in the city the need of pure milk for babies. The following year the Board of Health established fifty-five milk stations in the most crowded districts of Manhattan, Brooklyn, Queens, Richmond, and Bronx, where each week there are in attendance about 5,000 mothers with their babies, to whom about 37,000 quarts of grade A milk is sold. Each station has a trained nurse, assistant
nurse, and dispenser in daily attendance. During the winter months physicians hold clinics in each station twice a week, and in the summer months every day, to instruct the mothers in regard to the feeding and care of their babies. The nurses and their assistants follow up each case in the home, to see that the doctor's instructions are carried out and to further instruct the mothers in regard to the preparation of the milk and general hygiene in the home. There are in the city several other organizations, as well as some private individuals, engaged in this same work. Thus, the New York District Kitchen Association maintains eight stations, the Brooklyn Children's Aid Society fourteen, and Nathan Straus eight. Since such a large number of milk stations have been in existence there has been a decided drop in infant mortality, especially during the summer months, and we are hoping for still greater results in the future. Important as the lessened infant mortality for the past two years is, one cannot justly estimate the even greater importance of the lessened infant morbidity brought about. This can only be estimated in the years to come, when we trust that the better health and better development of the children in New York will prove the importance of right food for babies.

The following statistics obtained from the head of the division of child hygiene of the Department of Health may be of interest to you. In 1907, before this division was established, the death rate of young babies in New York city was 144 in 1,000; the following year the rate fell to 128 in 1,000; in 1910 the rate was 125 in 1,000. In 1911, when the New York Milk Committee instituted its campaign, the death rate fell to 112 in 1,000, and last year, after the establishment of the board of health milk stations, the rate fell as low as 105 in 1,000—a gain of thirty-nine per cent, in infant mortality.

WOUNDS OF THE PERICARDIUM AND HEART.

By Gray G. Holladay, M. D.,
Portsmouth, Va.

The rarity of wounds of the heart and pericardium terminating in recovery is my only excuse for reporting the three following cases:

Case I. On September 25, 1903, I was called at 7:30 p.m. to see a man (F. B.) whom, I was told, had been stabbed in the breast with a knife. Upon arriving, I obtained the following history: A short time before the stabbing he had had some difficulty with a fellow laborer, but on that occasion the two had been separated. Later as he was bending over in the act of lifting a cross tie, the knife was plunged into his breast from below and from right to left. He fell immediately, and was seized with a vomiting spell. He was so weak that it was thought that he would die at once, and his friends did not dare carry him home, although the house was not a great distance from where the stabbing occurred. However, later he rallied somewhat, and was then carried home, where I found him. The patient, aged nineteen years, was thin and short but muscular. His pulse was very irregular, weak, and intermittent; at times running as high as 120 beats a minute, at others as low as 78, or thereabouts. His countenance was drawn and haggard, his face bathed in a cold, clammy sweat, his respirations about normal. His voice was very weak and low; in fact, his whole condition was seemingly desperate, and it was with difficulty that he could talk at all. Upon examining his chest I found it was very small, clean cut wound over the sternum, on a line with the nipple in the middle line. Upon closer examination I found at the bottom of the wound a piece of metal firmly imbedded in the sternum, and just within its outer (left) border, slightly below the middle of the wound, after the bone had been tracted, and found it to be a portion of the blade of an ordinary pocket knife, between one and one quarter and one and one half inches in length. It had entered the bone from right to left. On the next day the patient's condition was somewhat better, his pulse stronger and far less irritable, but he was still very weak in every way, and his condition was precarious. On percussing his chest I found the area of cardiac dullness very much greater than normal. He complained very greatly of a severe cutting pain in his chest, saying that "to take a long breath nearly kills me." For several days he continued in about the same condition, except that the area of cardiac dullness increased, and gradually a fever developed, and a pleuritic area appeared with their usual signs and symptoms. He gradually improved and when I saw him on the morning of October 3d, I thought him much better, as all his symptoms had improved. On that afternoon I was sent for in a great hurry, the messenger told me the patient was dying, and that he had put him in a state of collapse, apparently from hemorrhage. The area of cardiac dullness, which had decreased to nearly normal, had again increased and continued to increase, his pulse was very rapid and weak but regular. His condition was caused by setting up suddenly, as he had layed somewhat but for some time was in a desperate condition. On November 20th he was able to be up. (Case published in American Medicine, September 16, 1904.)

Case II. This man, A. G., after shaving a knife, turned his 32 caliber revolver on himself, and, after firing it, fell across a sofa, seemingly dying. I reached him perhaps half hour later, and found him in the same condition. He was a large and powerful man, but at that time was unconscious, without perceptible pulse, and with very feeble and infrequent respirations, "rattling" in his throat, and bloody saliva flowing from his mouth. Upon examining his chest I found that the bullet had entered between the sternum and left nipple, breaking the fourth rib. His condition was so bad that I remained with him an hour and, during that time, I could feel, once or twice, a faint pulse at his wrist; but at the end of the hour his pulse was fairly good, having responded to stimulants, and his respiration had markedly improved. He was now removed to the hospital and at one put on the operating table. After he had received a few whiffs of ether, with the assistance of Dr. C. H. Barlow I opened his chest. The left pleural cavity was filled with blood, and a hole was found in the pericardium, but the bullet had not missed his heart, passing through his left lung and burying itself in the muscles of the back. Owing to the muzzle of the pistol having being pressed against his person, many grains of burned and unburned powder had been blown into his pleural cavity. I picked some grains of the pericardium and some off the surface of the lung; but some had been carried well into the lung substance. The hole in the pericardium was sewed up without drainage; the pleural cavity was washed out and drained; and the man put to bed. From this time on gradual improvement he became worse, and an abscess of the lung was diagnosed. A rib was resected under cocaine, and the abscess found and drained. After this the man improved very rapidly, and at one put on the operating table. He was discharged as cured on the 22d of December and went home, and went home, after the dangers of doing so were pointed out to him. When he left there was still a slight serous discharge from the chest. From this time on his condition continued to improve, and, from his good medical history, after he went home he had no attention, took no care of the drainage wound, nor of himself; the discharge later became purulent, and he died in about six months. I believe that the abscess in this case was caused by the powder which had been carried into the lung. After the operation the patient never had any trouble which
July 26, 1913.

LOBSENZ: ACUTE MERCURY POISONING.

By Jacob Munzer Lobenz, M.D.,
New York.

Many cases of acute corrosive sublimate poisoning have occurred due to swallowing of the drug, accidentally or with suicidal intent.

Death may occur in a short time from collapse, or, as is more common, from three days to four weeks after ingestion of the poison, in consequence of degeneration of parenchymatous organs, ulceration of the alimentary tract, and the resulting exhaustion. Yet recovery takes place in many cases, even after moderate degeneration. In those cases that run along for a week or two, ending either fatally or with recovery, a long train of symptoms are manifested, due to the irritant and corrosive action of the mercury.

In the following case, in which the patient recovered, there were symptoms with unusual features, and it is reported in detail, showing the progress from day to day. It is regrettable that it was impossible to find out how much mercury was retained and absorbed (after the emptying of the stomach) to produce the effects noticed, although the quantity swallowed was twenty-two grains.

CASE. Female, aged twenty-two years. Robust and in good health, swallowed three white bichloride tablets of seven and three tenths grains each. About ten minutes afterward the stomach was emptied by tube, and repeated-ly washed, with egg and milk, for one half hour. No signs of collapse. Patient complained of metallic taste in mouth; burning sensation in mouth, throat, and stomach. Constant vomiting. Twelve hours after taking tablets tongue and gums were deep blue, breath fetid. Tissues between the eyes were discolored. Iris red. Corneal injection, retinal hemorrhage.

On the second day, condition the same, with addition of coarse tremor of tongue and fingers; continuous pain and tenesmus. Two small bowel movements, with no show of blood; no urination.

Symptoms on the third day more aggravated. During the entire twenty-four hours she had twenty-seven bowel movements, all containing blood, mucus, and greenish fluid. About one half these movements were blood only, varying in quantity from one ounce to five ounces. Vomitus, blue fluid. Very restless. During night she had desire to void, was catheterized, and bladder found empty. No urination. From the fourth day on symptoms gradually diminished in severity. Pain, tenesmus, and bowel action decreased. Vomiting continuous. Deep ulceration of palate between uvula and left faucae. Liver, tender, enlarged, and palpable two fingers below costal margin. Abdomen very tender; no tenderness over kidneys. Voided about ten drops of blue tinged urine, containing no occult blood, at 3 p.m. on fourth day; this being the first kidney action in ninety hours, almost four days. No urination again for thirty-four hours, when an ounce and a half was passed. On sixth day blood ceased to appear in stool. Eight ounces of urine passed during the twenty-four hours. Urine excretion was 25 per cent. of total quantity, fifty ounces; acid, specific gravity, 1,088; albumin, a small quantity, a few casts; no sugar. Improvement marked, vomiting decreased, but still with bluish fluid. Marked erythematous blots appeared on eighth day over arms and legs, the trunk remaining clear. Urticarial wheals easily produced on body.

General improvement continued for the next week. Urine averaged sixty-five ounces daily, with small quantity of albumin and no sugar, till the fifteenth day, when 15 per cent. of sugar was found. Sugar continued to appear daily in smaller quantities for nine days, when it ceased entirely.

Patient discharged on twenty-fourth day as cured. During the whole period of sickness there were no signs of uremia and no indications of esophageal stricture.

The treatment followed was symptomatic, consisting of hot packs, wet cupping over kidneys, saline instillation per os, pilocarpine in doses up to one grain subnatum, and occasional tincture of opium, Vichy, and milk. After kidney action was established potassium citrate was given, in ten grain doses, four times daily.

Summary: After a patient has been removed from immediate danger of collapse and death a certain amount of degeneration must be looked for, as some of the mercury is retained and absorbed even after thorough emptying of the stomach. Interesting points in this case are: 1. Anuria for over five days, save for the passage of ten drops in the ninetieth hour; 2. temporary presence of sugar in urine for nine days; 3. bluish discoloration of fingers, toes, urine, and vomitus, without the ingestion of anything containing methylene blue.

In view of the fact that a number of cases of bichloride poisoning have been reported in the daily press of late, it would seem appropriate to remark that steps should be taken to prevent such poisoning by not permitting the dispensing of any poison for any purpose without the written prescription of a physician, and causing the containers holding a poison to be of a peculiar shape easily distinguished by touch, the cork of the container to be released only by some sort of a catch.

233 West 122nd Street.
Therapeutic Notes.

Treatment of Infectious Processes of Adenoid Origin.—A writer in *Monde médical* for January 15, 1913, discussing the treatment of acute inflammatory processes in the nasopharynx due to the presence of adenoids, states that when the condition is sufficiently severe to contraindicate early adeneotomy iodine preparations should be administered internally and the general system toned up with saline baths and rubbings.

Locally, preparations containing menthol are useful:

R Mentholis, ...... 1
Camphore, ...... \( \frac{1}{2} \) (0.15 gr.)
Olei olivae sterilisati, ...... 3vi (25 gr.).

Mische.

Or,
R Mentholis, ...... 1
Camphore, ...... 1
Eucalyptolis, ...... \( \frac{1}{2} \) (0.05 gr.)
Olei amygdale expressi, ...... 5v (20 gr.).

Mische.

These fluids should be dropped in the nostrils four or five drops on each side, at frequent intervals.

In the older children, ointments such as the following may be employed:

R Mentholis, ...... gr. iii (0.2 gr.)
Acidi borici, ...... 3ss (2 gr.)
Petrolati, ...... 3i (30 gr.)

M. ft. unguentum.

Or,
R Rosacrinol, ...... gr. viiss (0.5 gr.)
Acidi borici, ...... gr. xv (1 gr.)
Petrolati, ...... 3i (30 gr.)

M. ft. unguentum.

Inhalation of balsams through the nose should not be forgotten:

R Tincture benzoini, ...... 1
Tincture eucalypti, ...... 1
Alcoholis, ...... 3ss (40 gr.)

M. Sig.: One teaspoonful to be used by means of an inhaler.

Treatment of Gangrene and Suppurative Processes.—Blanchard, in *Bulletin médical* for March 26, 1913, reports good results from the use of ninety-five per cent. alcohol, diluted with one fourth part of boiled water, as a dressing for parts of the seat of gangrene. Thus, in a case of gangrene of the foot arising from infection of a toe, in which, after amputation above the knee, necrosis of the flaps had further taken place, dressings with alcohol clearly arrested the local morbid process and sepsis, fever, and pain disappearing within forty-eight hours, and healing later taking place under ordinary antiseptic dressings. Similar excellent results were obtained in a case of senile gangrene of the toe in which the process had extended to the leg notwithstanding other antiseptic dressings, and in a case of necrosis of the inner surface and dorsum of the foot due chiefly to trophic disturbances. In each instance pain was first relieved, then the discharge reduced and the part desiccated.

In extensive superficial suppurations, alcohol permits of reducing the frequency of the dressings when the latter cannot be attended to as often as desirable. Alcohol dressings may be left on six or seven days, and diminish pus formation. The granulations are more vascular, and repair takes place more rapidly.

In a case of diffuse phlegmon of the forearm, in which incisions and drainage had failed to prevent necrosis of areas of skin and partial destruction of one of the extensor muscles, the remaining portion of this muscle was dried and saved by the alcohol, and separation of the dead tissues facilitated.

The alcohol probably acts both by mixing the bacteria—as though to a glass slide—thus diminishing their number and virulence, and by drying the tissues, so that the organisms are imprisoned in them. The resulting solid mass can be readily removed with the scissors. In the living tissues alcohol does not induce the edema and swelling often brought about by ordinary dressings; hence there occurs more perfect vascularization of the fleshy granulations.

Treatment of Cases of Foreign Body within the Eye.—W. K. Rogers, in *Ophtalmology* for January, 1913, states that when the foreign body is metallic, not over three millimetres in area and not embedded in the posterior coats of the globe, the ideal procedure is to bring it forward with the giant magnet into the anterior chamber and out through the original wound if this is located in the cornea and is unsuited. The portable or auxiliary magnet should be used for delivery through a marginal incision, where the corneal wound has united, or through a posterior incision if the large magnet fails. Where the foreign body is as much as five mm. in area, is embedded in the posterior wall, or has entered through a wound which is still open back of the ciliary zone, the portable or auxiliary magnet is to be preferred.

Any metallic body back of the lens must be removed or the eye enucleated, for the safety of its fellow. While lead and nonmetallic substances are said to be better tolerated in the vitreous than other metals, the author believes prompt enucleation advisable in all cases of one eye uninjured.

Marked benefit appears to result when infected follow, as well as in sympathetic disease and all profound eye infections, from the employment of subconjunctival and deep orbital injections of mercury at intervals of from one to three days. The author's preference is for the following solution:

R Hydralgarvi chloridi corrosivi, ...... gr. i (0.06 gr.)
Sodii chloridi, ...... gr. x (0.6 gr.)
Acqua destillata, ...... 3i (60 c. c.)

M. ft. solutio.

Sig.: For subconjunctival or deep orbital injections of sixteen minims (1 c. c.) each.

Treatment of Puerperal Eclampsia.—J. F. Moran, in *Surgery Gynecology and Obstetrics* for February, 1913, states that while venesection is seldom practised nowadays in the treatment of eclampsia, in suitable cases it is one of the most valuable measures at our command. Where the blood pressure is high, with cyanosis, rapidly recurring convulsion, deepening coma, and threatened edema of the lungs, it is particularly serviceable. Its effect was strikingly shown in a postpartum case recently seen by the author, who is thoroughly convinced that the blood letting was the principal factor in saving the patient.
THE TREATMENT OF Erysipelas.

Although Pollatschek states that renal complications occur in about thirty-eight per cent. of all cases of erysipelas, more recent observations have shown that pathological urine is voided in such a large proportion of cases that it becomes a question whether the kidneys are not always the seat of inflammatory lesions. Of four hundred and eighty-three reports of cases of erysipelas examined by Boston and Blackburn, three hundred and twenty-seven showed pathological urine—a proportion over twice that recorded by Pollatschek. While renal complications are not deemed very serious as to their influence upon mortality, the fact remains that the latter continues high and that death shows a predilection for those cases in which albumin and casts are voided in relatively large quantities. Another morbid feature which may attend such cases, and to which attention was called last year by Lesné, Françon, and Gérard, is the occasional presence of a streptococcic septicemia, which almost always becomes complicated with infectious endocarditis. This involves the left side of the heart, the mitral valve becoming covered with small vegetations. It is often overlooked, physical signs denoting endocarditis being seldom detected in erysipelas. Nevertheless we have here another complication of no mean importance, one which also influences more or less the mortality of the causative disease. Erysipelas has yielded so little to treatment that the so called "expectant plan" and supportive measures have been advocated by not a few clinicians, the development of sufficient specific resistance on the part of the body being depended upon to check the progress of the disease.

There is good ground for the belief, however, that it is precisely in these neglected cases that renal and cardiac complications are apt to occur. To await, and depend upon, the development of an adequate specific reaction is virtually to sacrifice those patients who, through debility or age, are unable to awaken such a reaction. It is our duty promptly to institute measures which will enhance not only the autoprotective resources of the body at large, but also those of the cutaneous and lymphatic systems.

Of the newer local measures recommended in recent years, those in which heat is the predominant factor seem to have held their own. Hot compresses of saline solution frequently renewed (Ponzano) and the hot air douche, applied from one half to one hour two or three times a day (Ritter) have given good results—probably by increasing the efficiency of the lymphatic antibodies. Butter-milk applied with soft compresses, kept constantly wet, has recently been extolled by Arnold. An ointment composed of chlorinated lime, one part, and paraffin ointment, nine parts, is urgently advocated by Pinz. One older remedy, absolute alcohol, a powerful antiseptic, has recently gained many adherents. Magnesium sulphate in saturated solution has been highly praised owing to its ability to control pain, decrease the local hyperthermia, and prevent extension of the morbid process.

As to general remedies, the tincture of the chloride of iron seems to hold its own, but it is a question whether it does not, in the large doses usually employed, tend to promote the development of renal lesions. An immediate dose of calomel, to enhance the detoxicatory activity of the liver, has also maintained its reputation. Of the newer measures, diphtheria antitoxine, bacterial vaccines, and antistreptococcic serum, all have their sanguine advocates; but the salient feature upon which all men of experience insist is their early employment, i.e., before the pathogenic organisms have had time to initiate the lethal trend.
medical profession in the United States. The reasons for this supposition lie in the fact that Dr. Thomas R. Cullen, of Johns Hopkins University, in delivering the address in gynecology at the meeting of the Canadian Medical Association on June 25, made the propaganda for popular education as to the detection of cancer which is now being energetically carried on in this country a text for his discourse. Indeed, the address was more of a review of the proceedings in this direction in the United States than one on gynecology. Dr. Cullen, however, was well advised to impress the necessity for checking the inroads of malignant disease on a Canadian medical audience, and to point out how this could be brought about and was being brought about by the measures decided upon by the committee of eminent American surgeons appointed for the purpose as a result of the discussion at the Clinical Congress of Surgeons of North America held in New York in November last.

In the first instance, Dr. Cullen drew attention to the fact that, contrary to common belief, cancer was not a disease of the blood, nor was it incurable. In their early stages these malignant growths could be removed with safety, and the life of the patient saved. The difficulty was that the average man or woman paid no attention to the early symptoms and allowed the case to drift until it was too late.

It was in order, of course, to enlighten the community with respect to the early symptoms of the malady that the decision was come to, to make use of the lay press, magazines, and popular literature generally, as the most certain means of achieving this object. A most interesting account was given of the campaign that has been thus waged in the United States during the past few months, and, what is more to the point, Doctor Cullen vouched for the success of the campaign. Physicians from all parts of the country have reported that large numbers have come to them for treatment, urged to the cause by articles in the lay press and magazines describing the early symptoms of cancer in various parts of the body. The speaker wisely pointed out that if the women could be brought to recognize the necessity for having cancer cases diagnosed early the men would readily follow suit. The woman is the health guardian of the home.

It goes without saying that a very large proportion of those suffering from cancer seek medical advice only when the disease has gained a firm foot-hold, and it is equally obvious that had the malady been diagnosed in its early stages the mortality from the disease would have been greatly lessened. The argument, then, is logical and reasonable that if people, and especially women, were cognizant of the nature of the early symptoms they would seek skilled advice ere the time for successful treatment had passed. Even if some nervous individuals imagine that they have the disease when they are free from the taint, and seek professional advice when they have no cause for alarm, this drawback will be more than counterbalanced by the saving of health and life which will result from the successful treatment of those who were right in their surmise that their symptoms were those of malignant disease.

Viewed from this standpoint, the propaganda for educating the public as to the early symptoms of cancer appear to be justified. At any rate, the most eminent surgeons of the country are of this opinion. Doctor Cullen, at the end of his address, made an earnest plea that the Canadian Medical Association should inaugurate a campaign against cancer on lines similar to these in vogue on this side of the border.

**SYPHILIS AND HYPOCRISY.**

The evil consequences of syphilis are only too well known to a considerable proportion of the human race, but the general public has always tabooed the subject. Instead of intelligently facing this great problem, it has been content to adopt the method of the ostrich in the presence of danger, as though ignoring an evil would do away with its existence.

The recent play "Damaged Goods" might, from an optimistic point of view, be considered as a premonitory sign of a change of attitude by society toward this vital and perplexing problem. Nevertheless, a courageously intelligent and enlightened public viewpoint as regards syphilis is still a long distance off. The medical profession has always advocated the adoption of proper measures for the suppression or limitation of syphilis. Still, the public press, mirroring the prudish timidity and false attitude of an unenlightened people, has carefully avoided any references to a disease which has cursed the human race for ages. Hypocrisy and a sham modesty have acted as a cloak to cover up the ravages of this loathsome disease.

Sometimes one is inclined to rebel spiritually against the leisurely advance of human progress. But great bodies move slowly, and this is eminently true of society in its progress toward an open and fearless consideration of syphilis. Much could be accomplished in the way of diminishing the prevalence of lues were society willing to discard its cloak of sham, prudishness, false virtue, and hypocrisy. On rare occasions one may see in the public press vague allusions to this disease as "the social plague" or "blood disease." Why not come out in
the open and call a spade a spade? If we are striving for the good of mankind, there is no reason why the searching light of knowledge and education should not be directed publicly and broadly upon this disease. And therein lies the duty of the medical profession in the wider domain of social prophylaxis.

How long before we learn that publicity in dealing with a disease which actually and literally curses the offspring with the sins of its parents is the only way to approach one of the most vital problems for the betterment of the future race and the protection of the present? If it were made common and universal knowledge that practically no prostitute is free from venereal disease, and if the prevalence and horrors of syphilis were more thoroughly appreciated through means of widespread and nonhypocritical education in sexual matters, then fear, if not virtue, would help to reduce the prevalence of syphilis. If freedom from venereal disease were made a legal requisite for the privilege of marriage, another step would have been made toward the solution of this world problem. Education would, in time, bring us the voluntary self control of an enlightened race, and that would be far more potent than any statutes we could pass. Truth to say, we are dealing with a profoundly complex question, but if we desire to honestly reduce it to simpler factors, we have only one master weapon, and that is publicity.

THE BEDBUG IN A NEW ROLE.

Some months ago, in the Military Surgeon (September, 1912), Passed Assistant Surgeon R. E. Riggs, of the United States Navy, set forth in detail evidence that bedbugs act as carriers of typhoid infection. In 1910, he was stationed at a military post which was situated upon an island wholly isolated from any territory which might be suspected of harboring typhoid. This post had entire control of the traffic within its territory and complete supervision of its own food supply; its water supply was free from contamination and was unshared by others. Moreover, its history was free from typhoid. In every respect the post was ideally sanitary.

Typhoid suddenly struck down five men, however, with such steady aggressiveness that it began to look as if the whole garrison would speedily succumb. In searching for the source of the infection, the food, water, flies, drainage, and sewage were all excluded. Finally, by an analysis of the cases in the light of their mutual association, it was found that the first case was that of a prisoner who had been captured in a distant town where typhoid was endemic, and had subsequently been kept in close confinement in the brig before the onset of the disease. The second case was one of a prisoner who slept in an adjoining cell, while the three remaining patients had also been sleeping in the guardhouse. It was thus apparent that the brig was the focus of infection, and a careful examination was therefore made. It was found sanitary in every particular, except that bedbugs were present in immense numbers. These parasites and the air were consequently the only factors which the inmates had in common. In the belief that the bedbugs were probably at the root of the trouble, the building was thoroughly fumigated and thus complete extermination of the pests was effected. This was the only precaution taken to suppress the disease, but it proved sufficient, for no new cases developed, and there has never been a case of typhoid at the station since that time.

As additional evidence to incriminate the bedbug as a carrier of the typhoid germ, Riggs cites two other cases which came under his observation in private practice, and in which every other conceivable source of infection was eliminated. He therefore concludes that house epidemics, that is where one case after another in the same household occurs in communities which are free from the usual sources of infection, are, in the majority of instances, due to the activity of the bedbug. Looking back on many cases within his own experience, he was unable to find any other explanation so simple and convincing, and at the same time plausible, to account for the repeated appearance of typhoid fever where once it has gained a foothold in the family. While it must be obvious to all that this evidence adduced by Riggs is wholly circumstantial, it does not follow that it is to be lightly considered.

In this connection we should not forget the part which Dr. Carlos Finlay played in the history of the conquest of yellow fever. For a period of many years he kept telling a skeptical world that all the circumstantial evidence pointed toward the mosquito as the chief factor in the transmission of this disease, before he finally gained an audience of sufficient influence to compel an investigation which scientifically proved the correctness of his theory. In medicine, no less than in law, circumstantial evidence is often the most convincing.

AMERICAN JOURNAL OF TROPICAL DISEASES AND PREVENTIVE MEDICINE.

We congratulate the editor and collaborators of the American Journal of Tropical Diseases and Preventive Medicine on the first appearance of this journal. The importance of special study in preventive medicine has been felt for many years, and the medical profession will certainly welcome this
NEWS ITEMS

Aroostook County, Me., Medical Association.—At the seventh annual meeting of this association, held in Bangor recently, the following officers were elected: Dr. T. S. Dickinson, of Houlton, president; Dr. A. B. Hagerthy, of Ashland, vice-president; Dr. W. G. Chamberlain, of Fort Fairfield, secretary; Dr. W. E. Sincock, of Caribou, treasurer; Dr. A. J. Fulton, of Blaine, Dr. F. W. Tarbell, of Smyrna Mills, and Dr. F. O. Hill, of Monticello, board of censors.

Maine Medical Association.—At the annual meeting of the Maine Medical Association on July 31, the following officers were elected: Dr. W. S. Peters, of Bangor, vice-presidents; Dr. Eben Marston, of Bath, and Dr. C. T. Emery, of Biddeford, secretary; Dr. John B. Thompson, of Bangor; treasurer, Dr. E. W. Gehring, of Portland. The councillors, Dr. Stephen Webber, of Calais, and Dr. E. S. Dillahunt of Houlton. The next meeting also will be in Portland.

Representing the Chicago Medical Society at the International Medical Congress in London.—At a meeting of the council of the Chicago Medical Society held at the Hotel Shamian, the following were chosen to represent the society at the International Medical Congress to be held in London, England, August 6th to August 12th: Dr. Charles P. Caldwell, president of the society; Dr. John B. Murphy, Dr. W. L. Noble, Dr. Frederick Tice, Dr. C. A. Cotton, and Dr. J. A. Robson.

Mountainside Hospital, Montclair, N. J.—As a result of the successful campaign to raise $225,000 for Mountainside Hospital, Montclair, the managers have purchased all the land between the nurses' home and Bay Avenue, a total area of about five and a half acres, all of which is now available for the purpose of the hospital. As soon as the new buildings are erected all of the hospital buildings eventually will be grouped on the new site, with the decided advantage of moving away from the Erice Railroad. The amount paid for the land, including the buildings, is $75,000.

Vaccination against Typhoid Fever in Philadelphia.—Dr. Joseph S. Neff, director of the Department of Health and Charities, Philadelphia, stated, according to newspaper reports, that the Bureau of Health of Philadelphia was prepared to vaccinate with antityphoid vaccine all persons who might apply there for treatment. Owing to the presence of typhoid fever in Philadelphia and the fact that each year many cases of the malady were contracted by persons on their vacations away from this city, Doctor Neff recommended vaccination for members of families who did not carry out the instructions of the bureau and were exposed to the disease in their own homes. Summer tourists and vacationists who visited country districts or who might be otherwise exposed to typhoid contagion were also urged to be vaccinated.

New Medical School for Fordham University.—The new Fordham University School of Medicine will have a main façade 165 feet long and 100 feet deep. Four main laboratories are on the upper floors. There is a separate suite of rooms on the fourth floor for surgical research work. The first floor is on the fourth floor to be located the business offices, the library, and the laboratories of physiological chemistry, clinical pathology, physiology, and pharmacology. The equipment of the school throughout is of the most approved scientific nature.

Death of Physician while Attempting a Rescue.—Dr. W. F. Randall, one of the best known physicians in northern Pennsylvania, met his death on July 18th at Dushore, trying to save the life of a workman. He went down into a thirty-five foot well to rescue a digger, who had been overcome by gas and had fallen down 20 feet, plunging to the bottom of the excavation. He struck on his head and died in a few hours. The well digger was rescued by other persons and will recover.

Chattahoochee Valley Medical and Surgical Association.—The thirteenth annual convention of the Chattahoochee Valley Medical Association was held in Montgomer, July 15th and 16th. A large number of physicians and surgeons from Georgia and Alabama attended the convention. The address of welcome on behalf of the city was delivered by W. W. Skinner,ected as the speaker, while the address of welcome for the Montgomery County Medical Society was delivered by Dr. Philip B. Moss, Dr. J. M. Poer, of West Point, Georgia, responded to the addresses of welcome on behalf of the association.

Fourteenth Annual Meeting of the Lake Keuka Medical and Surgical Association.—The fourteenth meeting of Lake Keuka Medical and Surgical Association was held at Keuka, Lake Keuka, New York, on Thursday and Friday, July 17 and 18, 1913. The president, Dr. W. W. Skinner, expressed the pleasure of the association. The programme contained the following papers: Pyuria, by Dr. Viktor C. Pedersen, of New York. William Harvey and his Great Discovery, by Dr. Frederick W. Lester, of Medora, N. Y. Trachoma, Lues, and the Spine, by Dr. Clarence E. Coon, of Syracuse. Immunity: Its Relation to Modern Therapy, by Dr. La Rue Colegrove, of Elmira. The Relations of Internal Secretions to Surgical Conditions, by Dr. Roswell Park, of Buffalo. Gallstones. Considered as a Result of the Surgical Standpoint, by Dr. Nathan Jacobson, of Syracuse. Surgery of the Biliary Tract from the Standpoint of Results, by Dr. Homer J. Knickerbocker, of Geneva. Treatment of the Fixed Structural Type of Spinal Curvature, by Dr. Roland M. Monjack, of Buffalo. Kinds of Fever, by Dr. Clarence E. Coon, Rochester. Lantern Talk on Endoscopy of the Bronchi, Esophagus, and Stomach, by Dr. Chevalier Jackson, of Pittsburgh, Pa. Recent Advances in Cancer Research, by Dr. H. R. Gaylord, of Buffalo. Early or Precancerous Condition as It Is Found in the Breast, Lips, Tongue, and Stomach, by Dr. Williams L. Rodman, of Philadelphia. Manic Depressive Insanity, by Dr. W. H. Montgomery, of Willard.

Death Rate in New York City.—During the week ending July 5, 1913, there were reported 1,291 deaths and a death rate of 12.54 in 1,000 of the population, as against 1,273 deaths and a rate of 12.81 in the corresponding week of 1912, an increase of 18 deaths, but a slight decrease in the rate. Measles, scarlet fever, diphtheria, and whooping cough were the diseases most prevalent during the week of July 6th, but the number of deaths from the latter being 24° F. and a maximum of 89° F., compared with a mean temperature of 79° F., and a maximum of 95° F., of the week just passed. The infant mortality, notwithstanding the adverse weather conditions, was considerably less than that of the corresponding week of 1912, every borough showing a fall in the infant death rate, especially the Boroughs of Manhattan and Brooklyn. The infant mortality rate for the entire city during the past week was 8.39 as against 9.1 per 1,000 of the birth rate for the corresponding week of 1912, a decrease of 14 per cent. In the entire city there were 35 fewer deaths under one year of age and 45 fewer deaths under five years of age. The exceedingly hot weather which prevailed during the past week increased the mortality among the adults by 49 and among the old people over sixty years of age by 14. The death rate for the first 27 weeks of 1913 was 14.9 in 1,000, as against 14.09 during the corresponding period of 1912.
Abderhalden's Serodiagnosis in Psychiatry.—Wegener finds that the Abderhalden serodiagnosis is of great value for psychoses, and from this he expects important enlightenment on etiology, differential diagnosis, and, later, therapeutics also. His conclusions are the results of tests on two hundred patients suffering from all kinds of psychic disturbances. Numerous control tests were made in addition.

Lymphocytosis in Asthenics and Neuroathenics, and Its Clinical Significance.—Rudolf and Hoeslin say that the lymphocytosis is the same in obesity as in Basedow's disease, as well as in asthenic and neurasthenic diseases and many neurones. It points to a disturbance of the lymphatic system, and of the thymus and blood glands. The inclusion of these conditions in diathesis is justified if we understand by diathesis a constitutional status which is largely inherited. By this explanation the relation of the various diatheses becomes comprehensible. The favorable action of arsenic on some neuropathic conditions is referable to an influence on the lymphatic system, by which it removes the neutrophilic leukocenia and the lymphocytosis.

The Treatment of Amebic Dysentery with Emetine.—G. Baermann and H. Heinemann conclude that emetine is an exceedingly powerful amebotropic, amebozitic remedy, which, by subcutaneous or especially by intravenous administration, appears to destroy amebae contained in the intestinal walls, and in suppurating surfaces, as abscess walls. Amebas specially protected by location are spared. Total amebic destruction, as far as can now be observed, is only accomplished in very exceptional cases. Isolated single amebae usually appear again in from ten to seventy days; but in three patients there suddenly appeared evidences of numerous young amebae. In another, instead of the negative form, there appeared many cysts. The cysts are not affected by emetine. As a result of repeated emetine injections, abscesses which would otherwise prove fatal heal rapidly. As the best mode of administration the authors advise one or two intravenous injections, with 100 c.c. physiological salt solution, or combined with these, subcutaneous injections of from 150 to 200 milligrammes within eight or ten days, at from two to three days' intervals, according to the state of the patient. Later, from four to five subcutaneous injections of 100 to 120 milligrammes should be given. These after-treatments should be intermittently repeated in periods of from three to four weeks. Careful observation of the stools is absolutely necessary, and must be extended over a period of months. The maximum intravenous dose is 250 milligrammes for sixty kilogrammes of body weight.

Experience with Colloidal Palladium Hydroxydul (Leptynol).—M. Kauffmann says that leptynol is harmless, and that successful results were obtained with it in many patients suffering from disturbances of internal glandular secretions. The remedy acts most favorably when combined with a carefully watched diet. His best results were obtained in patients with extreme obesity who would not submit to a systematic course of treatment, but who, on the whole, adhered to restricted diet and fluids. Their weight was decreased from six to eight kilogrammes in four weeks. Five patients were reduced down to 10.5 kilogrammes within six weeks.

Treatment of Gastric Crises.—M. Fuchs says that when examining a patient with gastric pains the physician should never neglect to assure himself as to the possibility of tabes. The recognition of crises, when tabes is present, is an easy diagnostic matter. It is admittedly difficult when the crises appear as the first symptom of tabes; but, having tabes in mind during the examination, the diagnosis is made possible by other accompanying symptoms. Many an unsuccessful gastroenterostomy would not be done if the operator had first thought of the possibility of tabes. Lumbar injections of novocaine suprarenin have given relief for six months at a time. These may be repeated with good results on return of the crises.

The Diagnostic Significance of Ferments as Foreign Substances in the Blood.—E. Abderhalden says that every kind of cell shows peculiarities in the method of its metamorphosis. Each cell has its own specific function, as it has its own peculiar architecture. Fischer likened various kinds of ferments to different kinds of keys, and the substrata to be acted upon he compares to locks. Exactly as a certain key opens only a certain kind of lock, so will a certain kind of ferment attack and change only certain compounds in cells or open cell walls in order to devour their contents. Abderhalden therefore agrees that when specific ferments are set in motion each kind of cell is influenced to dominate over specifically constructed parts. The author is experimenting with these proofs. Each cell is capable of rendering asusids parts of its own makeup. It must thus govern its ferments, contained in these cell parts. This line of thought, though important, is not yet generally understood. Even though results are already attained, it must not be forgotten that only modest progress may at present be spoken of. The author is working with materials (ferments) which are not familiar. Only the action of the ferments is known. When the ferments themselves, as such, are known, and the substrata can be well defined, the investigation will be complete.

A Contribution to the Study of Experimental Endocarditis.—Fox reports the results obtained by injecting into rabbits of virulent streptococci procured from the tonsils of a case of rheumatic angina and a case of puerperal sepsis. The organisms from the two cases were injected into the ear veins of rabbits, and valvular lesions developed. It
seems probable that the primary lesion may have been in the myocardium at the base of the valve, and, by extension, caused the vegetative endocarditis.

April 19, 1913.

The Action of Repeated Injections of Salvarsan and Neosalvarsan on the Blood.—Karl Hedj studied the effect of repeated injections of “600” on the blood of luetic patients. His conclusions are not uniform. The polymorphonuclear leucocytes seem to be unaffected. In some cases the eosinophiles seem to be increased and in one case decreased. In the majority of cases the blood pressure rises; also the red cells are increased, while the white cells remain about the same.

**Zentralblatt für Gynakologie.**

June 7, 1913.

The Diagnosis of Tuberculosis by Means of Guineapigs.—Bauereisen calls attention to the difficulty of making an early diagnosis of tuberculosis of the kidney. When guineapigs are used it generally necessitates waiting from four to six weeks for the development of tuberculous lesions that can be recognized microscopically or with the unaided eye. The method recommended by the author consists first in the injection of the suspected material, intraperitoneally, subcutaneously, or directly into the liver. In the course of from two to three weeks the animal is given an intracutaneous injection of tuberculin. Within twenty-four to forty-eight hours there will be a characteristic local reaction. Experiments indicate that the intracutaneous is more accurate than the subcutaneous method. The time of appearance and severity of the reaction have a direct relationship to the degree of tuberculous involvement.

Palliative Treatment of Inoperable Carcinoma with Powdered Sugar.—Berezelle recommends the use of powdered sugar, claiming that the odor and discharge rapidly decrease, the bleeding lessens, and conditions in general improve so much as to make one believe that healing is taking place. The treatment at first is given daily, then from one to three times a week.

June 14, 1913.

A Case of Repeated Extrauterine Pregnancy.—Von Lingen reports a case in which the patient had an extrauterine pregnancy in the left tube. This ruptured, and was removed by operation. Seven years later the right tube with its contained ovum was removed.

June 21, 1913.

The Biological Diagnosis of Pregnancy According to Abderhalden’s Method.—Parsamow reports his results with Abderhalden’s dialysis method in one hundred and sixteen instances. The author gives in detail his technic and tabulates his results. He concludes that a positive reaction is constantly present in those who are pregnant. As one obtains similar reactions in the nonpregnant, it is evident that the test is not a specific one and can be of relative importance. A negative reaction indicates that there is no pregnancy, but a positive one does not necessarily imply that such a condition exists.

June 28, 1913.

The Calcium Content of the Blood in Pregnancy.—Linzenmeier gives a brief report of his experiments upon this matter. He finds that the blood of women during the second half of pregnancy always shows an increased amount of calcium. He believes that the pregnant woman not infrequently is given a diet that does not contain a sufficient amount of calcium, and he therefore gives a table showing the amount of calcium in grammes that is contained in a kilogramme of different forms of food. If the mother does not receive a sufficient amount of this salt she must therefore supply it from her own tissues, to their detriment.

**Archives des Sciences Biologiques, St. Petersburg.**

Vol. XVII, No. 2.

The Hemolysin of the Bacillus Subtilis.—M. N. Margoulies found the Bacillus subtilis to produce an extremely active hemolysin, which is thermostable. The hemolysis this body causes is manifested not only in the escape of hemoglobin from the red blood cells, but also in granular disintegration of the latter. In view of the fact that the hay bacillus is widely distributed in the atmosphere, and on the surface of the human body, Margoulies is led to suggest that this bacillus may be the cause of certain cases of anemia, and even of acute chlorosis of unknown origin.

**Paris Médical.**

June 21, 1913.

Atypical Syphilis.—H. Guergout points out that energetic treatment of syphilis, with either salvarsan or mercury, is capable either of delaying the outbreak of secondary symptoms, without diminishing their intensity, of both delaying the secondaries and limiting them to a few cutaneous and, in particular, mucous membrane lesions, or finally, of suppressing all secondary symptoms and producing an apparent clinical cure. After suppressing or attenuating the secondaries, such treatment seems sometimes to hasten the advent of tertiary symptoms, or rather, the early recurrences, instead of consisting of secondary manifestations, are tertiary in nature, generalized syphilitic disturbance having been prevented and the infection tending to become localized. Cases of this kind, of which the author reports several, should render the physician more careful than ever in pronouncing a case of syphilis cured. The patients should be kept under watch and treated, even when apparently cured, as false cures are still more frequent than is generally thought. Cases of syphilis of long standing should be examined twice yearly, even if there are no symptoms, and given treatment if the Wassermann test is positive. Lumbar puncture should be practiced yearly in order to detect nervous disorders in their earliest stage, and be able, probably, to prevent their further progress.

Causé of the Paroxysms in Epilepsy and Asthma.—Arthur Leroy invokes the physical process of dialysis to account for epileptic and asthmatic attacks. In the case of the former, the
PITH chemical true lesion.

LANCET. (3), the bacillus inflammatory the tubal lasting producing gonnq inition.
The plicated imisms, intestines, of tuberculosis bacillus being sometimes masked by gonococcic, streptococcic, colon bacillary, or tetragenic infection. He divides cases of pure tubal tuberculosis into (1) the granular, miliary, peritoneal, and ascitogenous form; (2), therogenous or pus producing form; (3), the lardaceous or infiltrated and ligneous form, and (4), the polymorphic form, consisting of combinations of the preceding. Tubal tuberculosis may be complicated by other organisms, which may reach the tube either from the intestine, the genital tract, or the blood. The author reports a case complicated by tetragenus infection, in which large bulke filled with serum fluid were prominent fractures of the pathological specimen obtained at operation. On the other hand, chronic tubal affections of ordinary type may become complicated by tuberculosis. Microscopical examination is practically a sinea qua non to diagnosis where tubal tuberculosis is complicated by other infections. In the surgical treatment of the condition the author advises conservation of the uterus and ovaries—a plan which proved very satisfactory in the cases under his care.

Estimation of Urea in the Blood.—L. Hu-gounenq and A. Morel recommend the use of a method first described by Fosse in 1907, consisting in the precipitation of the urea, in urine diluted with alcohol, with xanthylhydr or diphenopyranol. The test is specific, i.e., urea alone will lead to the formation of a precipitate; no delicate manipulation is required, except the weighing of the precipitate on a chemical balance, and the procedure can be carried on with comparative rapidity, especially where several estimations are to be made at once.

X Ray Treatment of the Nerve Roots in Neuralgias.—A. Zimmern, P. Cottenot, and A. Dariaux report that the application of the Röntgen rays to the nerve roots has yielded constantly good results in the treatment of sciatica, as well as of neuralgia and neuritis of the brachial plexus and trigeminal nerve. Their clinical material consists of thirty cases. Not only was radical radiotherapy found to exert a pronounced analgesic action, but there was a reparative action, shown in the return of reflexes such as the tricipital or the Achilles reflex. The authors are convinced that whether the condition responsible for the neuralgia be a true radiculitis or a lesion compressing the nerve roots, x ray treatment frees the latter from the surrounding pressure. Where the neuralgia is due to involvement of the nerve trunk peripheral to the radicular region, the x rays fail. The dose of the rays given by the authors at each sitting varied from one half to three heat units, according to the sensitiveness of the patients. The apparatus was so disposed as to bring about oblique penetration of the rays to the spinal roots, between or through the vertebral laminae; the opposite side, beyond the spinous processes, being protected by sheet lead. In sciatica the irradiation should be directed to the last two lumbar and first three sacral vertebrae; the sacroiliac joint may also be treated. If the cause of the sciatica is suspected to be a true radiculitis, the entire region should be treated, up to the spinous process of the eleventh dorsal vertebra. For brachial neuralgia, the rays should be applied between the third cervical and first dorsal spinous processes, while for trigeminal neuralgia they should reach the region above the zygoma, in the vicinity of the ascending process of the malar bone.

JOURNAL D'UROLOGIE.

April 15, 1913.

A New Method of Diagnosticating Renal tuberculosis.—Leo Buerger gives the history of a case in which cystoscopy showed an edema of the left ureteral orifice and the left portion of the trigone. The right ureter was catheterized and normal urine obtained. Catheterism of the left ureter was impossible. The bladder urine contained pus, but tubercle bacilli could not be found. The Buerger operating cystoscope punched out the edematous area, and this on section showed tubercle bacilli and a miliary tubercle.

Calculi of the Parietal Part of the Ureter.—Pastuau emphasizes the diagnostic importance, when a calculus is arrested in the intravesical portion of the ureter, of the bulbous edema (sometimes massive) which surrounds the ureter. This symptom, together with renal colic, or dysuria, is sufficient basis for the diagnosis of ureteral stone arrested at the ureteral orifice. In five cases which gave this symptom complex, and in which stones were proved to be present, either by operation or by passing spontaneously, the radiograph was twice negative.

Lancet.

July 5, 1913.

Incarceration of the Cecum and Ascending Colon in Lesser Sac of Peritoneum.—Ivor Baek's patient, a man, aged 41, was taken suddenly ill with acute pain in the right half of the abdomen, chiefly in the upper portion. He vomited at the time. After a few hours of comparative mildness of pain, a dose of black draught brought on a severe recurrence, together with a return of the vomiting. The pain was paroxysmal. No flatus or feces had been passed since the onset of symptoms. Pulse 125,
temperature 96° F., and respirations 32. The abdomen was retracted and rigidly fixed on the entire right side; the left upper portion was also rather tense. No mass or swelling was to be found, even under anesthesia. The diagnosis was made of perforating appendicitis with spreading peritonitis involving the right side of the abdomen. The intestines and peritoneum were found normal when the abdomen was opened for appendectomy, but neither cecum nor ascending colon was found. A second median incision in the upper abdomen revealed a mass which was taken for the gallbladder. Puncture of this, to relieve distention, liberated gas having a fecal odor and so relieved the tension that a knuckle of gut, which had passed through the foramen of Winslow and then ruptured through the gastrohepatic omentum, so as to lie under the parietal peritoneum, could be extracted. It was found that the entire cecum and ascending colon had passed through the foramen of Winslow. After suture of the puncture which had been made, the involved gut was freed and the abdomen closed after its proper replacement. The patient made an excellent recovery and his cecum and colon are apparently at present in their proper positions.

On the Possibility of Achieving by Partial Pneumothorax the Advantages of Complete Pneumothorax.—W. Parry Morgan argues that at the site of a tuberculous focus in the lung there is an area of tissue which is less expansile than is the surrounding lung, and hence the elastic portions of the lung along any axis which passes through such a focus must be stretched abnormally, to compensate for the lack of elasticity, during the process of breathing. This often leads to a certain amount of localized emphysema, and certainly materially aids in the maintenance of activity in the focus and tends to promote the spread to other portions of the lung. If a comparatively small amount of gas be introduced into the pleural cavity it will reduce the general inthoracic tension and in inspiration the normal portion of the lung will still follow the thorax, but the introduced gas will collect over the area of diminished elasticity and will thus accomplish its immobilization. Precisely, these phenomena can be demonstrated to occur in a partially consolidated lung artificial thorax preparation. It matters not whether the tuberculous lesion be single, or whether there be several more or less scattered lesions, the introduction of a small amount of gas—that is, the production of a partial pneumothorax—will accomplish the purpose of putting the affected region at rest. Such a condition is the desired aim of artificial pneumothorax, but when this is complete the entire lung is subjected to uniform conditions, and soon it can be shown to be following the respiratory movements, although greatly collapsed. Under such conditions the diseased tissue is not so effectively immobilized as when the pneumothorax is only partial.

BRITISH JOURNAL OF DERMATOLOGY.
May, 1913.

Epithelioma and Rodent Ulcer Occurring in the Same Patient.—Haldin Davis reports this case chiefly because of its rarity. He also quotes several other instances occurring in the practice of other dermatologists.

A Case of Multiple Telangiectases.—J. H. Sequeira describes an unusual case of telangiectasis rather widespread and associated with hemorrhages. He discusses at length the various types of telangiectasis, and concludes with a dissertation on the etiology of this affection.

PRACTITIONER.
June, 1913.

Some Points in the Treatment of Bronchial Asthma.—Arthur Latham says that there can be no question that light cauterization of the septal nerve of the septum in suitable cases, adequately carried out, produces great relief in a large proportion of the patients. He has seen a number of patients in whom this procedure has been carried out by capable men. In few instances does it cure, for its effects are seldom permanent; but in a large number it gives great relief, which may last for several years. It rarely does harm, except when polypi have previously been removed. Such cauterization can act only by virtue of diminishing the capacity of dust and odors for stimulating unduly sensitive nasal nerve endings, and so inducing a reflex effect upon the bronchial tubes.

Nasal Disease in Relation to Asthma.—Dundas Grant examined the nose in 107 cases of asthma and found the conditions such as to call for operation in sixty-eight, to be abnormal but not to call for operation in thirty-one, uncertain but probably adenoids in one, and no nasal abnormality in seven. From a study of these cases and of the literature on the subject he concludes that when nasal disease is present, even allowing for the rare occasional increase of temporary discomfort, the coincidence of asthma is an additional indication for operation. Many of the disappointments are due to the obstructive nature of the nasal disease.

Asthma in Children.—Eric Bellingham Smith presents an interesting study of asthma as it appears in children, which presents two distinct types, one met with under five years of age, the other in older children. The drugs used fall for the most part under two headings: 1. Sedatives and hypnotics: 2, antispasmodics. Their administration has also to be considered under two headings: 1. During an acute attack; 2, during the intervals. If the attacks occur only at night he gives a mixture of potassium iodide, belladonna, and ethereal tincture of lobelia, to be given at bedtime. It is safe to give one half grain of iodide for each year of life, from two to ten minims of tincture of belladonna from infancy to ten years old, and lobelia in minim doses for every year of life, up to five minims. If the attacks occur day and night he gives the same prescription, in rather smaller doses, three times a day. He thinks that iodides will be found to be the sheet anchor in this disease in early life; when they fail it is rare to get relief with other drugs. Iodides should be given regularly for from six to eight weeks, then left off for a fortnight and replaced by a tonic, such as arsenic; then renewed; in this way the effects of the iodides is prolonged. When other drugs have failed he thinks that perhaps a little improvement can be obtained from the liquid extract of grindelia. He doubts if calcium does much good, but if four or five minims of epinephrin are added to
it some parents seem to think that distinct relief may be gained. Hot baths seem to have a sedative effect in an infant, and some persons still swear by the old fashioned steam kettle, the steam from which may be mediated in various ways. An injection of from three to five minimis of adrenaline, 1/1000, can be given. If the child is very bad, nascent oxygen, and perhaps a very small dose of morphine sulphate, 1/30 grain, might be given. He has never used that drug in asthma, and never uses any of the sedatives except a little bromide or antipyrine, when the child is definitely overexcitable. Errors in clothing should be corrected firmly but tactfully.

**CANADIAN MEDICAL ASSOCIATION JOURNAL.**

June, 1913.

**Puncture of the Corpus Callosum.—**Edward Archibald gives the technic of this operation as follows: On the right side, about a finger's breadth behind the coronary suture and two cm. from the median line, an opening is made with the Doyen burr, about 1.5 to two cm. in diameter. A slit opening is made in the dura, and care is taken to avoid any large cortical vein. Then a curved hollow cannula is pushed over the convexity of the cortex till it strikes against the falx, which membrane guides the further progress of the cannula downwards till the corpus callosum is reached. The instrument breaks bluntly through this structure with very slight force, whereupon the ventricular fluid is emptied, usually under some pressure. An average of from ten to thirty c. c. of fluid is evacuated, but in cases of marked hydrocephalus as much as seventy c. c. Von Bramann advises enlarging the hole by pushing the cannula forward and backward, over what distance he does not say. The operation is recommended for all cases of hydrocephalus which defy internal treatment and have not been ameliorated by lumbar or ventricular puncture; for all cases of tumor or pseudo-tumor of the brain accompanied by hydrocephalus and optic neuritis; and finally for decompression as a preliminary measure to extirpation of tumors. He then reports four cases on which he has performed this operation, two of hydrocephalus and two of unlocalizable tumor. In the latter cases two methods of decompression were employed, for neither alone was sufficient to obtain the best results. He thinks that callosal puncture promises to be a satisfactory operation for decompression in many cases of tumor, especially in the presence of a complicating hydrocephalus. In his two cases of obstructive hydrocephalus of high grade in the infant callosal puncture proved temporarily of slight benefit, but ultimately failed to relieve the condition.

**Tuberculosis of the Genitourinary System from the General Practitioner's Standpoint.** — William Hutchinson divides cases of tuberculosis of the genitourinary system into four groups: 1. Early acute cases; 2. early mild cases; 3. late cases, but unilateral; 4. late cases, bilateral. In the first group, that is in those cases where the symptoms are very acute, the bladder much swollen, and the ureters difficult to locate, the treatment should be the same as in acute pulmonary tuberculosis. The patients should have absolute rest in bed, should be kept in the fresh air and in as dry a climate as possible, and should have nourishing diet, but not large quantities of fluids, to put as little strain as possible on the kidneys. Tuberculin should be given, commencing with a dose of 0.0001 milligramme. This dose should be repeated once a week until two or three have been given, and then the strength should be gradually increased to 0.001 milligramme. If the symptoms are aggravated by one of these increasing doses the advance must be stopped and smaller doses given. By this means the disease may become quiescent, or at least the acute symptoms will subside, and then the treatment will be the same as that for group three. The second group should be treated in the same way as the first, except that absolute rest in bed is not necessary, though no violent exercise should be undertaken, and the doses of tuberculin may be increased more rapidly. It is important to examine these patients from time to time to see whether the condition is improving, for if not, an operation is imperative. The treatment of the third group is purely operative. The kidney is exposed by a loin incision, and if there is difficulty in exposing it, or any danger of breaking the abscesses, a transverse incision should be made toward the abdominal cavity through the muscles, but not through the peritoneum, thus obtaining sufficient room to ligate the pedicle without difficulty. The ureter should be followed down and excised as near the bladder as possible. Before cutting through the ureter a ligature is placed around it, and later the cut end is cauterized in order to destroy the mucous membrane and thus to aid in a firm union. When the bladder also is involved, tuberculin should be employed subsequent to the operation for a considerable time, but no local treatment can be undertaken. The cases in group four can only be treated in the same manner as those in group one. Operation, save for a nephrotocectomy with permanent drainage in order to relieve extreme bladder symptoms, is out of the question. The treatment of tuberculosis of the testicle should, at first, be along general lines, combined with the use of tuberculin, but if this is not successful, the testicle should be removed, and if the vas deferens is thickened at all it should be followed down to the seminal vesicle. Primary tuberculosis of the bladder and prostate must be treated on general principles, no operation being advisable.

**INDIAN MEDICAL GAZETTE.**

June, 1913.

**Ankylostoma Ceylanicum, a New Human Parasite.** —Clayton Lane found in the stools of three patients ankylostomes that were shorter and thicker than the *Ankylostoma duodenale* and were finally identified with the ceylanicum discovered in 1911 in the civet cat by Looss, and since found in Bengal in dogs and cats, as well as in lions. It does not appear to be a common human parasite.

The Action of Treponema pallidum from the Brains of Paretics to the Rabbit.—Hideyo Noguchi has proved experimentally that typical syphilitic sclerosis containing Treponema pallidum have been produced in the testes of rabbits, in two instances, by the inoculation of an emulsion of the brain of a paretic individual. The development of the lesions was slow, in the one instance ninety-two days and in the other one hundred and five days. The proportion of successful inoculations has been small; they were obtained with one brain out of six. As regards the tardy development of the lesions, and also the low proportion of infections, the result is striking when contrasted with the results of the inoculation of chancres, condylomata, or secondary syphilitic papules. By using several rabbits the writer has usually succeeded with every specimen of the latter, while he has been successful, in the former, with only one specimen of brain out of six used. The small number of pallida present in the brain tissue may explain the disparity; it may be due to a low degree of infectiousness of the brain spirochetes for the rabbit. The percentage (17), however, is about that (25) in which the pallidum has been detected by histological methods in the brains of paretics.

Injection of Boiling Water in the Treatment of Hyperthyroidism, by Dr. Miles F. Porter.—See this Journal for July 5th, p. 38.

The Relation of Gastrostomy to Inoperable Carcinoma of the Esophagus.—Henry H. Jane way emphasizes the point that experience has demonstrated that gastrostomy in properly selected cases prolongs life, and for a long time in many patients contributes considerably to their comfort. Moreover, it has frequently happened that a carcinomatous esophagus has again become pervious after the rest afforded by a gastrostomy. The writer describes in detail the technic of a new method of performing this operation, which results in the formation of a long canal from three to four times the length of the two short incisions at the extremities of the first cut. The effect is to cause the stomach wall, at the place where the tubular canal is formed, to lengthen out very markedly, the split rectus fibres coming together around this canal and acting as a sphincter. The new canal when formed has an oblique direction to the left, and any increase of intragastric pressure will bring the walls of the fistula together and effectually prevent the escape of stomach contents. In five cases operated by the writer, in accordance with the technic described, the proximal end of the new canal has never been inverted, the new canal being simply sewed near its base to the margin of the opening of the rectus sheath and the mucous membrane of the external opening of the canal to the skin, depending entirely on the constricting influence of the rectus fibres and the oblique direction of the new canal for tight closure. In none of the cases has there been any appreciable leakage.

The Action of So Called Emmenagogue Oils on the Isolated Uterus. —With a Report of a Case of Pennyroyal Poisoning.—David M. Mcllch brings out forcibly the poisonous properties of pennyroyal, exemplifying the same by the history of a case brought to his notice. He concludes, from experiments made on the isolated uterus of the cat, that the so called emmenagogue oils are by no means innocuous substances. They have absolutely no direct stimulating action on the uterine contractions or tonicity, but, on the contrary, they inhibit such contractions, and even paralyze the uterus.

Their action as abortifacients, if they act as such, is no different from that of any other powerful systemic poison, such as phosphorus or arsenic. Finally, they (pennyroyal, savine, tansy, rue, thyme, apioi) have little if any therapeutic value and are not worthy of a place among the official pharmacological preparations.

What Relation, If Any, Have the Fauclal Ton- 
sils to Pulmonary Tuberculosis?—E. Fletcher Ingals observes that a decade ago it was commonly believed that tonsillar disease was a frequent cause of pulmonary tuberculosis, but subsequent research has apparently proved that tubercle bacilli may enter and pass through the tonsils and cause disease of the cervical lymph nodes, while the tonsils themselves may escape all injury. This research has also shown that there is no direct connection between the cervical lymph nodes and the pulmonary lymphatics, and therefore, that involvement of the lungs associated with cervical adenitis must be a systemic infection rather than a result of lymphatic disease. The writer concludes by confessing that his belief is that there is no relation between the tonsils and pulmonary tuberculosis.

When and How to Use Nitroglycerin.—Edward E. Cornwall emphasizes several points in connection with these questions. The general indications for the use of this remedy are to relieve symptoms of localized arteriosclerosis or arterial spasm in vitally important regions of the body, and, when there is pain due to contracted or diseased arteries, in other regions; to reduce general high blood pressure if its continuance threatens accidents to the cardiovascular system; and to clear the diagnosis. The chief contraindications to its use are either a low or a relatively low blood pressure; advanced chronic nephritis with very high blood pressure and toxemic conditions producing high blood pressure, as a rule; and the presence of an idiosyncrasy in regard to its action. It should never be used primarily as a heart stimulant. When placed under the tongue effects are as prompt as when injected subcutaneously. If given too long or in too large doses it can produce injurious effects, which, however, disappear when the remedy is discontinued.

MEDICAL RECORD.

July 12, 1912.

Metabolism and the Circulation.—Alexander Haig lays stress on the fact that the circulation controls the life of the whole body. The functions of the skin, the heart, the kidneys, the liver, the salivary glands, the stomach, the intestines display phenomena which testify to the fact that all their
functions are most intimately related to a free circu-
lation in their capillary vessels, which bring nour-
ishment and remove waste products, and generally
provide for the life of the tissues from moment to
moment, which we call metabolism or combustion,
the results of which are heat, brain power, energy,
and in short, life. An excess of waste products in
the blood (collemia) increases the work of the heart
and diminishes its power, and in this way depresses
the metabolism and combustion of the whole body.
Urea, the chief nitrogenous waste product of the
kidneys, produces the same effects. The writer
shows the influence of these two factors in produc-
ing conditions which have been named as diseases,
but which diseases disappear when the causative
collemia and uric acid have been eliminated. In
this connection he refers to the production of
anemia, the so called "bilious attack," headaches,
purpura rheumatica, Bright's disease, etc., by these
agencies, and he suggests that there is here no dis-
case, but a condition representing various stages of
poisoning by one substance which is not contained
in the natural food of man, and with which he has
come into disastrous contact only through an unwise
departure from his natural food. By controlling
the uric acid, together with the heart power, we can
produce any desired change in the circulation, and
except when it has produced structural change, we
can remove its effects. By controlling the uric acid
every function of the body is controlled, including
the nutrition of the heart and lungs, and the life of
the entire body is under our control, and we can do
with it what we will.

Psychogenic Disorders; Cases Seen in De-
tained Immigrants.—Howard A. Knox, from a
study of this subject, with reported cases, con-
ducts that psychogenesis is important in considering
whether or not a given psychosis is founded on
degenerative soil and hence whether the cause of a
given alien's insanity existed prior to landing.
Cases occur in which psychoses have arisen in
healthy persons with apparently normal nervous en-
dowment. Psychogenic disorders are important
to all who are identified with medicolegal problems
since most of the psychoses of criminals are psy-
chogenic in character. In making accurate diag-
noses and especially diagnoses in traumatic and
other organic mental dis-eases or supposed diseases
of this nature a knowledge of psychogenic dis-
orders is requisite. Finally, immigrants suffering
from psychogenic disorders should not be ex-
amined for defectiveness while in this state, and
lay workers with no knowledge of medicine, psy-
chiatry, or neurology, are not competent to detect
these conditions, but would call such a patient
"stupid" or rate him as "seven years old on the
Briet."

The Present Status of Esophagoscopy in
Cancer of the Esophagus.—Richard Lewisohn
insists that the direct inspection of the lesions of the
esophagus is the most certain method for exact
diagnosis, that early diagnosis in cancer of the eso-
phagus is possible only by working along these lines,
and that it is only by means of early diagnosis that
successful operative results may be looked for.
Until a few years ago cancer of the esophagus was
looked upon as a hopeless condition. The discovery
of Saubruch has changed the outlook. The writer
is sanguine that further work in this field will
eventually make it possible to resect a cancer of the
lower esophagus as successfully as the surgeon to-
day excises a carcinoma of the cervical portion.

AMERICAN JOURNAL OF THE MEDICAL SCIENCES.
June, 1913.

Clinical Observations Concerning Twenty-
seven Cases of Spleenectomy.—H. Z. Griffin gives
consideration to a series of twenty-seven cases in
which splenectomy was done, and is impressed with
the fact that a proper classification of conditions in
which marked splenic enlargement is associated with
secondary anemia is extremely difficult, if not im-
npossible, at the present time. The best basis for a
tentative classification is the clinical features, as they
assist us in recognizing clear cut and uncomplicated
cases of splenic anemia. As the pathology of splenic
anemia and other conditions simulating it is but lit-
tle understood, it is best, for the present, to base our
conclusions only on those reported cases in which
both pathological and clinical evidence have been
published. The review of these cases would suggest
a possible relationship between gallbladder disease
and splenomegaly and the existence of a clinical
syndrome presenting a picture embodying our con-
ception of splenic anemia in which splenectomy is
followed by a return to excellent health in a large
proportion of cases, but in those instances in which
the diagnosis is complicated by other diseases of a
chronic infectious nature, the value of splenectomy
is doubtful. In these, as in other medicosurgical
conditions, it is imperative that the physician ac-
quire himself thoroughly with the details of sur-
gical prognosis. It is only after a careful diagnosis,
not only of the enlargement itself but also of the
patient's general condition, and after the elimin-
ation of the existence of serious complications, that splen-
ectomy should be advised.

Observations on the Intestinal Bacteria in
Pellagra.—From the report of the Illinois State
Pellagra Commission on the fecal bacteria in pel-
lagra a brief summary is made by W. J. MacNeal.
The fecal bacteria in pellagra, when subjected to
direct microscopical examination, are found to dif-
fer from the normal in the quantitative relation-
ships, and are associated with unusual kinds of bac-
teria, more or less heterogeneous in nature. The
cultural tests developed unusual quantities of
certain normal types, Bacillus bi'ndus, Bacillus Welchii,
and micrococi, as well as a great variety of bacterial forms not usually found in
healthy human feces. None of these changes
appeared to be constant. During the acute at-
tack accompanied by diarrhea the Gram positive
coci were nearly always more numerous, and the
Gram negative bacilli less numerous than normal in
these cases. These changes, also observed in the
subacute cases and persisting to a slight degree after
the skin lesions were healed, were nearly con-
stant and were such as might naturally follow the
digestive derangement. There was no indication of
a substitution of the normal intestinal bacteria by an
abnormal invader. The abnormal types were varied
in number, and in no case dominant in numbers. Sub-
cultures were made from numerous colonies, and
one hundred of these bacterial strains were sub-
jected to agglutination tests. Two of these bacterial
strains, Nos. 14 and 67, appeared to be identical. The writer undertook the task of isolating further bacterial strains from the intestinal contents of pellagrins. While his work is not yet completed, he has failed to isolate any germ similar to strain No. 67 (mentioned above) from the feces of these new cases. From the duodenal fluid, however, a few strains have been obtained which have given positive agglutination tests with the serum of pellagrins, and which seem to agree biologically with strain No. 67. No definite conclusions are drawn by the writer, as his investigations are still incomplete.

The Rational Treatment of Tetanus, with a Report of Twenty-three Cases from the Episcopal Hospital, Philadelphia.—Astley P. C. Ashhurst and Rutherford L. John agree that tetanus is a pure toxemia. The bacilli or their spores may exist indefinitely in the tissues, and no symptoms will appear unless toxins are formed, and if the toxine is introduced into the system, the characteristic symptoms of tetanus will be produced, even though no bacilli are present. The toxine ascends the nerves through the axis cylinders (perhaps by means of a centripetal protoplasmic current), and in this way can produce a severe tetanus, ascendsens; the toxine may be transmitted through the perineurium and endoneurium, and be a factor in producing local tetanus; the toxine also spreads to neighboring parts of the cord, invading its sensory portions, and also entering the circulation (this last eventually reaches the cord and produces descending tetanus). The most important feature in prophylaxis is the early and efficient care of the wound, and the prophylactic use of antitoxine at once, a second injection about the eighth or tenth day; and a third during the third week, in each case to be made as near to the wound as possible, so as to flood the tissues, and deep, so as to permit its rapid absorption; while if any nerves are exposed in the wound they should be injected. The prophylactic dose should be 1,500 units. The writers say of "Fourth of July tetanus" that in spite of diligent and unprejudiced study, they are not convinced that such injuries are more liable to be followed by tetanus than other contused or lacerated wounds. The reduction in the incidence of tetanus they attribute as rationally to better care of the wound as to the antitoxine employed.

The Use of Antityphoid Vaccine during the Course of an Epidemic.—C. J. Hunt concludes from his studies made in an epidemic that antityphoid vaccine has little value in limiting the number of cases and in modifying the process in the individual case. It would seem that a serum would be of some advantage during such an epidemic, since antityphoid serum confers relatively a more immediate and fairly strong immunity. The use of vaccine should be limited to those not already infected, that secondary cases may be prevented. The individual history and diagnosis by culture would determine its use.

Acute Polymyositis.—Herbert Fox reports the blood culture finding in a case of acute polymyositis, which is interesting in that it is another case to support the view that this disease is a bacteremia due to a micrococcus, with curious and rather uniform predilection for the musculature by which a subspecies or variety of a pus former can produce a definite clinical picture, with more or less characteristic lesions differing from those produced by the most prominent member of the group to which it belongs. It is suggested that the infection assumes the form of polymyositis when a Micrococcus pyogenes bacteremia occurs in a person whose condition favors rheumatism, although there is no pathological basis for this, as the lesions are different.

AMERICAN JOURNAL OF OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN.

June, 1913.

A Critical Review of the Medical and Surgical Treatment of Puerperal Eclampsia.—Zinke discusses at length the relative values of the medical and surgical methods of treating puerperal eclampsia. Inasmuch as the character of the causative poisonous substances is absolutely unknown, although all authorities agree that in the majority of cases eclampsia results primarily from renal insufficiency, there is little to be done in a direct way. Certain writers take the stand that as eclampsia depends upon pregnancy, the emptying of the uterus is the most important factor in bringing about the recovery of the patient. Consequently, the advice of these men is to bring about delivery after the first attack. Zinke, in going over the reports on the subject, concludes that the surgical method, by Caesarean section or otherwise, does not offer any advantages, and that under many conditions it is unjustifiable. He considers the medical treatment to be comparatively simple, dividing it into the prophylactic and the curative. If his method fails he believes that very little could be expected from surgical intervention. The good results obtained from strictly medical care in these cases far exceed the results accruing from all the surgical means proposed for relief from this condition.

Some Obstetric Observations Pertaining to Internal Secretion.—Good reports the cases of two patients, one a primipara of twenty-seven, the other of a multipara of forty-two, who, after simple spontaneous labors, died within a few hours of vasomotor paresis. The pulse ran up to from 150 to 180, and was irregular and thready; this was followed by a drop to about sixty-five, with low tension. A number of somewhat similar cases reported by other men are also mentioned. Good calls attention to the frequency in which thrombosis or embolism is given as a cause of death, and how infrequently it is found in cases coming to autopsy. He comes to the conclusion that it seems more probable that this cardiovascular collapse is due to some marked disturbance of internal secretion, the lack or excess of some hormone, an increased or diminished secretion of a ductless gland. The adrenal is the gland that is considered mainly responsible.

Complement Deviation by Corpus Luteum Antigen.—Knowing that the ovary possesses a powerful influence over the nervous system of the individual over the development of the uterus and of the breasts, and over the phenomena of menstruation, Smith wished to determine if such an "internal secretion" would produce an antibody. If so, might
it not be possible to determine the presence of such an antibody by a complement deviation test, using as antigen an extract of corpus luteum tissue? His experiments, however, proved negative.

A Contribution to the Study of Eclampsia as a Toxemia of Possible Mammary Origin.—Wilson reviews at some length the parturient paresis of cattle and its resemblance to eclampsia in the human being. Following this he discusses the literature dealing with cases of eclampsia that were treated as possibly being due to a mammary toxemia. From a comparison of the two conditions he concludes that there is not very much in common, and that the mammary theory of eclampsia does not rest on a firm basis.

X Ray Treatment of Uterine Fibroids, Menorrhagia, and Metrorrhagia.—Stern gives the results obtained in the treatment of fifty-two cases. Although it is by no means a cure all, he believes that a large proportion of cases can be cured, and others benefited, by the treatment, but there are cases where it will fail, despite careful and energetic persistence. Sometimes the improvement does not begin till the fourth, or even the fifth, month. There seems no danger of producing a permanent menopause in women who are not near the climacteric period. In younger women temporary menopause, lasting in some cases more than eight months, has been followed by a reestablishment of menstruation, generally in a normal manner.

The Newer Operations for Restoration of the Pelvic Floor, with an Original Technic for Exposing and Uniting the Injured Levator Ani and Deep Transversus Perinei Muscles.—Hirst, by means of a number of most excellent pictures, illustrates a new operation for this condition. By means of his new method Hirst believes that the restored pelvic floor has a more normal feel and affords a firmer support than can be obtained by any of the other operations at present in vogue.

AMERICAN JOURNAL OF SURGERY.
May, 1913.

Radiographic Diagnosis of Syphilis, Tuberculosis, Tumors, and Osteomyelitis of the Long Bones.—W. M. Brickner avers that a careful analysis of every radiograph will in nearly all cases reveal the diagnosis. Two reactions characterize the radiographic picture of syphilis. The most constant and most distinctive feature is thickening of the periosteum. The second and next most important feature is the thickening of the bony tissue, especially the cortex. Both of these produce black shadows on the x ray plate. A third type of process, which may appear, by contrast, as a light area, is gummatus destruction of the bone. The writer quotes Ware in contrasting the radiographic features of (hereditary) luetic and tuberculous dactylitis: Tuberculosis originates in the epiphysis, syphilis in the epiphyseal end of the diaphysis. In tuberculosis there is little or no periosteal thickening, in syphilis the periostitis is marked. In tuberculosis there is a greater tendency to bone destruction, in syphilis to bone production. In tuberculois the swelling is largely due to inflammation of the soft parts, in syphilis it is largely due to thickening of the bone. Suppurating sinuses are not uncommon in tuberculous dactylitis; they are in syphilitic dactylitis. In chronic osteomyelitis of pyogenic origin the x ray may show well defined periostitis, but slight as compared to syphilis. The involucrum, often seen in chronic pyogenic osteomyelitis, does not occur as such in syphilis, and, as compared with the new bone produced in the latter, it is usually thinner; its borders are also thin and irregular. Endosteal sarcoma presents a characteristic marked rarefaction in the tumor area, expansion of, and shelllike thinning out of the cortex. Periosteal sarcoma may be easily mistaken for syphilis, but the shadow in sarcoma is often blotchy, wavy, or fringelike, and, instead of hugging the bone as in syphilis, it may appear to radiate from it like miniature swirls in a sandstorm.

Ligation in Hyperthyroidism.—George M. Todd has employed the following method in ligating the thyroid vessels in twenty-six cases without fatality: A skin incision is made an inch and a half in length along the anterior border of the sternoclavomastoid muscle, the upper extremity of the incision being the lower border of the cricoid cartilage. The sternomastoid is exposed, and, just to the inner side of this muscle, we find the anterior belly of the omohyoid, while inside of this muscle is located the sternothyroid. These muscles are retracted, the sternohyoid to the inside of the omohyoid and sternomastoid to the outside. By blunt dissection the anterior surface of the thyroid gland is brought into full view by separating the muscles from its capsule. The carotid vessel is now exposed and the thyroid gland, covered with its uninjured capsule, lies in the field before one. With slight traction upon the gland, the superior thyroid artery is to be seen at the upper angle of the wound, leaving the carotid and entering the gland at its upper extremity, and the inferior vessel deep in the lower angle, entering the gland on the posterior surface, about one third of an inch distance upward from its lower extremity. A full curved round needle, threaded with number two chromatized catgut or ironed silk, is now passed with the arteries in full view, being certain to include sufficient tissue, whereby the lymphatic structures and the nerve supply of the gland may be included with the artery.

ARCHIVES OF INTERNAL MEDICINE.
June, 1913.

Histopathology of the Nervous System in Pellagra.—H. D. Singer and L. J. Pollock report the findings noted in a series of fourteen cases of pellagra. The gross morbid anatomy of the nervous system was in no way characteristic. Microscopically, there was found in the acute pellagra attack, as well as in the interval cases, a picture compounded of both acute and chronic types of reaction. The acute changes included chromatolysis of nerve cells, the presence of ameboid glii cells, and slight perivascular infiltration. The chronic changes included fatty and fibrinoid degenerations, chronic Nissl changes of the nerve cells, increase of glii fibres, permanent destruction of nerve fibres, and a marked increase of amyloid bodies. In common with other intoxications, the acute pellagra attack was found to give rise to a "central neuritis" reaction. None of the changes detected by the authors
are considered by them characteristic of pellagra. They conclude that there is no evidence of a local infection of the nervous system with microorganisms, nor that chronic vascular changes are essential to the picture of pellagra.

Influence of Rapid Changes in Altitude on Blood Pressure.—F. E. Clough studied this question in 100 normal miners, who went down a shaft 1,700 feet deep in two minutes in the morning, and up the same shaft in one minute at the close of the day's work. The rapid change in altitude, either up or down, was found to cause a fall in blood pressure of about five mm. of mercury. Lower pressure readings, in general, were obtained from the age decade thirty to forty than from twenty to thirty. It was impossible to forecast by a man's build or any other factor what influence the ride would have upon his blood pressure. Abnormally high blood pressure was shown not to be a contraindication to hard work under ground.

Superpermeability in Nephritis.—W. A. Baetjer writes concerning four cases of nephritis, similar in that while the elimination of sodium chloride was impaired, the tests with lactose and phthalein showed a supranormal excretion of these substance. He concludes that there exist cases of well marked nephritis with impairment of renal function in which certain tests reveal an eliminative power which is normal or even above normal. These cases may be more common than has hitherto been supposed, judging from an experience of four such examples in several months. The evidence suggests that there may exist in some types of nephritis a stage in which the kidney is superpermeable, at least to some substances. It is necessary to study renal function from the standpoint of a considerable series of functional tests, rather than to draw conclusions from the excretion of any one drug.

Auricular Fibrillation, with Post Mortem Examination.—A. E. Cohn and J. D. Heard report a case in which, when auricular fibrillation appeared, a fall in the ventricular rate from 120 to 80 occurred. Strophanthin, administered intravenously some weeks later, exerted a strikingly beneficial effect on the circulation and subjective symptoms. The post mortem examination showed a lesion of the sinoauricular node, but it could not be definitely asserted that a relation existed between the lesion and the clinical irregularity.

Relation of Heart Block to Lesions of Auriculoventricular Bundle.—H. E. B. Pardee refers to a patient with aortic and mitral insufficiency and normal heart action who developed complete heart block and died. Autopsy showed a streptococcus endocarditis superimposed on a chronic process of the aortic valve which had involved the heart substance. The auriculoventricular bundle had been destroyed for one half of its transverse section by the chronic process; but this, so far as known, had never produced heart block. The complete block had been caused by acute inflammation of the whole auriculoventricular system. The author concludes that the extent of the anatomical changes is not the only factor inducing heart block. Bacterial and metabolic toxins and deficient local blood supply are suggested as accessory factors which, under certain circumstances, might act alone.

REPORT OF CASE OF ACANThOSIS NIGRICANS.—Herman G. Klotz and George L. Rohdenburg report a case of acanthosis nigricans previously exhibited by Doctor Klotz before the New York Dermatological Society. It was that of a man of sixty-four years, who previous to 1910 was healthy. Early in that year he noticed a change in the color of his skin, and the scalp became itchy. Later on, pigmentation of various sizes and roughness of the skin appeared in various areas. Wartlike areas were also found scattered over the skin and also on the tongue. General examination at that time was negative. Ultimately a diagnosis of cancer of the sigmoid was made. The patient died, and an autopsy made revealed a small, spindle cell sarcoma involving almost the entire colon and also secondary deposits in other organs. The case confirms the general experience that in elderly patients acanthosis nigricans is always associated with malignant tumor of abdominal organs. The unusual location of the primary tumor is of interest and explains why it remained undiscovered until a late period.

REPORT OF A CASE OF EXTENSIVE TUBERCULOSIS CUTIS, WITH DEATH FROM PYEMIA.—Henry Kenedy Gaskill lays stress on the mortality of generalized tuberculosis cutis. He shows the unreliability of the statistics of this affection. He shows that in his case, as also in cases reported by Kaspari and Crocker, generalized tuberculosis cutis, particularly when occurring on the lower extremities, sets up a toxic (tuberculous) lymphangitis which ultimately leads to fatalty. He describes his case in detail.

SOME DETAILS IN WASSERMANN TECHNIC.—Arthur William Stillians discusses several phases of the Wassermann reaction, and gives the following conclusions: First, that a standard scale of recording strength of reaction should be adopted and that the proportion of hemolysis offers such a scale. Second, that titration of luetic antibody is necessary to accurate knowledge of strength reaction. Third, that several antigens should be used for each test. Fourth, that absorption of native amboceptor detects a considerable proportion of positive reactions that would otherwise remain undetected or doubtful, and does not cause a positive reaction with nonluetic sera. That it is of value and should be used to parallel the Wassermann reaction in negative or doubtful sera with large amounts of native amboceptor. Fifth, that we should not allow ourselves to build upon the assumption that a negative Wassermann reaction means a cure.
Verruca Peruana: Its Comparative Histological Study in Man and Ape.—In this very full paper, H. N. Cole concludes that in cases of this disease with three successful reincubations in monkeys, no specific organism had been found, and also that in man, as well as in apes, the tumors found resemble each other very closely in their mode of formation, in their constituents, and in their gross appearance.

Negative Wassermann Reaction in Untreated Tertiary Syphilis of the Skin and Mucous Membranes.—O. H. Foerster records two undoubted cases of tertiary syphilis of the skin and mucous membranes, one occurring in his practice, and one in the practice of his associate, which gave negative Wassermann reactions; and throws out a hint of warning in reference to an absolute reliability of the complement fixation test of lues.

OPHTHALMIC RECORD.

June, 1913.

A Case of Gumma of the Iris after the Use of Salvarsan.—Aaron Brav reports a case in which a man twenty-four years old received an intravenous injection of salvarsan because of syphilis contracted five months before, and had no other treatment. Six weeks later he suddenly developed severe pain in the left eye, accompanied by photophobia and lachrymation. Four days later Brav found the left eye red, with a marked ciliary injection, the cornea clear, the pupil about two m. m. in diameter, with a very slow reaction to light. On the margin of the iris there was a circumscribed reddish brown growth as large as two pins heads, with a small adhesion to the anterior capsule of the lens. The pupil dilated under atropine, except at the point where the tumor was situated. Under atropine, leeching, and mercurial inunctions, the tumor rapidly disappeared, and the eye was perfectly well at the end of two weeks. (The history of the case, the stage of the syphilis, and the nature of the remedies to which the tumor responded, make it highly probable that the diagnosis should read, papule of the iris. Gummata of the iris are rare, but they are sometimes met with in the tertiary stage of syphilis and they respond best to large doses of potassic iodide.—Editor.)

Enucleation under Ciliary Ganglion Anesthesia.—Jesse S. Wyler proceeds in the following manner: The patient is prepared as in other operations and five drops of a four per cent. solution of cocaine are instilled into the conjunctival sac at intervals of two minutes. A syringe holding one c. c. is fitted with a strong needle exactly five c. m. long, and filled with a 0.9 per cent. solution of cocaine and 0.1 c. c. of epinephrin (one in 1000). The speculum is inserted to make the canthus tense, and the needle is entered exactly in the angle of the external canthus, close to the bony edge of the orbit. If the needle is sharp it penetrates easily about 1½ c. m., and then strikes the lateral wall, when the direction is turned nasally, following the wall closely until the penetration has gone the entire five cm. of the orbit. By gently swaying the syringe it can easily be determined that the point of the needle is free in the orbit, and not caught in the periosteum. The mixture is then slowly injected, the speculum removed, and after about three minutes considerable pressure is made over the ciliary body, which will cause no pain if the anesthetic has reached its goal. The eyeball is protruded a little when the injection is made. Enucleation can now be made in the ordinary manner. Local anesthesia for this operation is particularly to be preferred in patients in whom the use of general anesthesia is contraindicated for any reason.

Proceedings of Societies.

THE AMERICAN GYNECOLOGICAL SOCIETY.

Thirty-eighth Annual Meeting, Held at Washington, D. C., May 6, 7, and 8, 1913.

The President, Dr. Henry C. Cor, New York, in the Chair.

(Concluded from page 154.)

Further Report of Cases of Dysmenorrhea Relieved by Nasal Treatment.—Dr. Joseph Brettauer, of New York city, said that after an experience of two and one half years with the nasal treatment of dysmenorrhea, the final results showed that about one half the number of cases so treated the results were favorable. In some cases the benefit was temporary, requiring another course of nasal treatment. In other instances the relief was prompt and permanent after one or two caustic applications to the nasal spots during a menstrual interval. A report of sixty-six cases so treated was included in the paper.

Dr. Emil Mayer, of New York city, stated it had been his privilege to see the cases reported by Doctor Brettauer, and also quite a number of others which he had not seen fit to include in his report, because he was not sure of some of the conditions presented. Some of these cases were in patients of his own. Occasionally a young woman would come to his office with intermenstrual disturbances, and naturally being interested in the question of painful menstruation, he elicited from such that they had suffered a great deal at their periods, and, following treatment of the nasal conditions, he was able to benefit them; so that his own statistics, which he hoped to publish later, would be more favorable than those of Doctor Brettauer. As to amenorrhea, he had had several young girls who had not menstruated at all for three or four months, but after applications to the nose menstruation became established.

Dr. E. C. Dudley, of Chicago, said he would like to ask if the author of the paper was to be understood as holding that this cautery treatment of the nose should be used in all cases in which there were neither pelvic nor abdominal symptoms. In other words, if examination of the pelvis and of the nasal passages were found negative, would he then empirically cautereize?

Dr. Henry T. Byford, of Chicago, stated that one of the chief objections he had to this method was the indefinite-ness in regard to the kind of dysmenorrhea and the condition of the nose. As he understood, there had been no study made of the kind of dysmenorrhea to be helped. There were no lesions of the nose except during the menstrual period, or when congestion appeared during the menstrual period and they were usually regarded as a result, and not as a cause of something; and when women had pain in their breasts every month, we did not treat the breasts, thinking we would cure any disturbance in the pelvis. There were a great many cases of dysmenorrhea, and one of these had not been spoken of, namely, nervous dysmenorrhea. He was willing to concede that the treatment outlined by Doctor Brettauer would help patients who had this form of dysmenorrhea.

Dr. Robert C. Myles, of New York city, said he found many cases of serious local irritation in the nose where the central nervous system seemed to be in a state of aggravation or irritation as a result, with resulting phenomena in other parts of the body; and when this irritation in the nose was relieved the other symptoms or phenomena disappeared.

Dr. W. Gill Wylie, of New York city, stated that after a long study of this subject he had come to the conclusion
that in many of these cases the underlying cause was imperfect development of the lining membrane of the uterus. A peculiar case came under his observation not long since. A man brought his young daughter to him, and when he asked her what the trouble was, she said that about the time of menstruation, or when it was approaching, her daughter could not appear in company, especially if there were gentlemen about, because suddenly her lips became so large and her face so red that she felt very uncomfortable and uneasy. He studied the case and told the mother he thought she could make a diagnosis. The girl was put on the table, with the mother and nurse present, and on examination he found little or no abnormal changes in the vulva, and concluded that the girl was not pregnant. He did not detect any gross disease, but he noticed the secretions about the vulva to become very profuse. He had found, when examining women, that if an erotic feeling was excited by the examination of the cervix, there were marked changes in the erectile tissue of the genitals.

Doctor Breitta said, in answer to Doctor Dudley’s question, he would say by all means touch the nose in the absence of any pathological condition in the nose and the pelvis. He would do so as an experiment, as it could do no harm.

The Conduct of Gynecological and Obstetrical Operations in the Presence of Acute or Chronic Endocarditis.—Eugene P. D. Haines, New York, gave the following conclusions as summarizing his experience in gynecological operations under such conditions: 1. In pelvic conditions necessitating operation this may be done under ordinary preparation. 2. The cardiac symptoms, the blood pressure, the functions of the liver and kidneys, are the only indices of when it is time to operate. 3. These cases should always be seen and treated in conjunction with a competent internist. 4. These cases may be complicated by anemia, and should be treated with combined local and general anesthesia (morphine novocaine, ether, and oxygen). 5. The Trendelenburg posture should be used only until such time as the field can be properly isolated, when the patient may be gently lowered out of the Trendelenburg posture and promptly replaced in the right heart engorgement. 7. Postoperative distention must be avoided. 8. Morphine was the mainstay in the perineum.

The Influence of Ectopic Pregnancy on the Blood Supply of the Uterus, with Special Reference to Uterine Bleeding: Based on the Study of Twenty-five Injected Uteri Associated with Ectopic Pregnancy.—Dr. John A. Sampson, of Albany, New York, stated that as a result of examining the vasculature of the uterus, it was found mainly to hyperemia and a thickening of the endometrium. The changes in the latter were similar to those found in the decidua vera of early uterine pregnancy. The venous spaces of the endometrium were dilated and this dilatation was made more prominent by distention of the compact layer and at its junction with the spongy layer. The termination of the pregnancy was followed by involution of the uterus. The first step in the involution of the endometrium was seen in the greater dilatation of the venous spaces, probably due to regressive changes in the stroma and apparently dependent upon a diminished supply of arterial blood to the arterioles of the endometrium. If the superficial venous stasis of the compact layer gave way, the blood would escape into the uterine cavity, without the formation of a deciduoid cast. On the other hand, if the venous spaces at the junction of the compact and spongy layer were dilated, the extravasation of blood would occur mainly between these two layers, and the compact layer would be expelled as a deciduoid cast. In time the regressive changes ceased and were followed by a reparative process which was characterized by thickness of the endometrium and restoration of the arterial supply of the endometrium. The involution following the termination of tubal pregnancy was very similar to that following uterine pregnancy, differing only in degree. In the cases of ectopic pregnancy the complete termination of the pregnancy was a gradual process often taking several days or weeks, four weeks or more in seventeen of the twenty-five cases studied. When operated on the uterus had been and might still receive stimuli from two distinct antagonistic sources, namely, pregnancy and involution. The condition present in any case depended upon which of these sources predominated and to what extent it had been and was influenced by the other. The uterine bleeding was usually due to hyperemia of the endometrium, and due to regressive changes in the latter, apparently dependent upon a diminished arterial supply. Muscular insufficiency might also contribute to this. The bleeding continued as long as the pregnancy (products of conception) remained in the tube. This was probably analogous to the bleeding in subinvolution of the uterus due to an incomplete uterine abortion.

Dr. Philander A. Harris, of Paterson, New Jersey, said that to one who had performed a good many operations for ectopic gestation, and on which circumstances he had based his opinion, it was interesting to have this unquestionable demonstration of the changes which occurred in the uterus. It would not have been possible for him to exhibit uteri from the cases on which he had operated for ectopic gestation, excepting those that were also the seat of some constitutional disease, to bring up the question of what practical use was the uterus after an operation for a simple gestation? Doctor Smith of the society had collected a good deal of valuable information along this line, but he hoped he might be pardoned if he referred to the operations of John M. Paterson, 228 on whom he had operated who gave birth to children. In thirteen of these the ectopic gestation was recurrent. The only point which came to his mind now was whether, in order to secure only four or five offspring in thirty-six cases of ectopic gestation, he had been successful in bringing the operation to cure the rectocele as was employed in the modern radical operations for the cure of cystocele; the rectum was completely separated from the entire posterior wall of the vagina and was placed higher in the pelvis. The author described the operation and gave the technique used by him in perineorrhaphy.

The Relation between the Blood Pressure and the Prognosis in Abdominal Operations.—Dr. George W. Crile, of Cleveland, Ohio, stated that the relation between the blood pressure and the prognosis in abdominal operations was based upon two extremes, an extremely low blood pressure and an extremely high blood pressure. Provided the heart was normal, we could now control the low pressure phase by transfusion of a hyperchloral solution. The high blood pressure was far more difficult to control, because it was difficult to control the factors that produced it. If there were cardiovascular disease due to infection or to lues, nitroglycerin might exert little control, although there was a type of cardiovascular disease that was controlled by nitroglycerin. It was not wise to reduce the blood pressure by bleeding, and aside from nitroglycerin and hydric measures, there were no other remedies. Therefore, as a matter of fact, the worse the condition the more dangerous factor was than low blood pressure. Whether the blood pressure were abnormally high or abnormally low, the patient was more apt to have complications such as thrombosis, embolism, pneumonia, nephritis and uremia—which indeed were entered into the hands of all the usual dangers and complications of abdominal operations. If operation were so performed that the nervous system remained uninjured, the blood circulation unaltered, the maximum or optimum safety would be reached. This lie had found could be done on the principle of anoci association.

Studies in Blood Pressure before, during, and after Operations under Local and General Anesthesia.—Dr. Joseph C. Bloomfield, of Baltimore, Maryland, said that even to-day, with better anesthesia, with better technique, we had a mortality. The mortality was not from simple ap-
pendectomy and from other simple operations, but from the
greater operations, such as resection of the stomach, resec-
tion of the colon, the more extensive operation for

cancer of the uterus, and the more difficult operation for

metastasis. Now and then, after the operation, when there
was an autopsy on such a patient we might find no
infection of the wound, no break in the technic of the
intestinal suture, no hemorrhage from the pelvic operation,
though still the patient had died in a few hours. Of course,
why such patients died was as a rule within forty-
hours or three days with a gradual lowering of
blood pressure, with a gradually increasing pulse, with
little or no fever, or that they died from complications
with which we were not prepared in this particular case.

Complications of the Heart, Complications of the stom-
ach, such as dilatation. There was this mortality in surgery
to-day which had no relation to infection and no relation
to circulation, or to shock or death from complications
that were due to shock of the operation. These complica-
tions were chiefly dilatation of the heart, dilatation of the stom-
ach, and faulty kidney function. He was trying to show in a prac-
tical way how we were being forced to investigate as to how
we should operate on these cases in the future, as a result of the
investigation of the literature on the subject, and stimulated by
Doctor Crile's work in the laboratory and clinic; he had attempted to follow
the technic, and he thought the most practical thing he could say
for the operation today was to lay down principles. We should
remember, however, that to accomplish something that was difficult, something that was more than ordi-

ey, we must practise. From his experience, now cov-

ered by his successors, he believed that if we wanted to develop
the technic of anesthesia and operation, and to give these
patients handicapped with an extraordinary operation the best
opportunity for recovery we must practise this newer technic in every case until we had gotten it fully

developed.

The Diagnostic Value of the Electrocardiograph before

Gynecological and Obstetric Operations.—Dr. Hugo H.
Freund, of Detroit, Michigan, gave a short de-
scription of his instrument and spoke of its application to
hospital cases, especially those in which the patient's car-
diac condition was in doubt. He showed lantern slides
demonstrating the various forms of cardiac irregularities
as recorded with the electrocardiograph. The advantage of
this instrument in the hands of those who have not
inside examination and over certain forms of sphygmo-

graphic tracings was discussed. Some stress was laid
upon the type of electrocardiograph that called for opera-
tive interference in pregnant women.

The Calcium Metabolism, also of Pregnancy and Labor in Acute and Chronic Affections of the Heart.—Dr. J.
Clarence Weisberg, of Chicago, said operations should be avoided in active or recent val-
"lar diseases, dilatation, or myocardial degeneration, ex-
cept in conditions of extreme emergency. General anes-
thesia might greatly increase the risk by causing cough-
ing, straining, vomiting, or respiratory embarrassment.
Slow administration with free admission of air or oxygen was
said to be the best means of preventing this, but in such cases.
In slight or well compensated affections regular
methods of anesthesia might be employed. As re-
gards pregnancy, women with heart disease should not
become pregnant. If pregnancy occurred, it was consid-
ered advisable to advise early abortion, especially if there
was recent acute disease of any variety, or old mitral dis-
ease of other lesion with failure in compensation. With
reference to labor, if the patient's condition was good, in
this first stage, as local anesthesia all of it in normal exist-
ence should be avoided. It was advisable to avoid strain-
ing in the second stage by artificial delivery, forceps, or

turning under anesthesia. In the third stage it was best to

partially relax and then allow sufficient or several drops
of liquid blood. A woman at term carrying a placenta in complication,
or embarrassed circulation probably had the best chance if
delivered by vaginal or abdominal Cesarean section.

The Significance of Anemia as an Operative Risk.—
Dr. Henry Byrnes, of Chicago, stated that for surgical
purposes we might divide cases of anemia into two groups

namely, those with compensation and those without. The
former class were good operative risks, the latter poor ones.
He pointed out the characteristics and compli-
cations of each, and cited illustrative cases. The

Treatment of Peritonitis and ThromboPhlebitis.—Dr. Pal-
mer Findley, of Omaha, Nebraska, reported ten cases, re-
viewed the literature on the subject, and went on to say
that with this review of his recent personal experience with
peritoneal thrombo-phlebitis, he wished to call attention
upon the fact that a diagnosis of an accurate diagnosis before opening the abdomen were
as yet insurmountable; furthermore, it was not possible to
judge with accuracy the extent of the infection within the
veins or elsewhere after the abdomen was opened. The

problem would be to diagnose with certainty the limits of a thrombus, nor could we judge with certainty the absence of a thrombus, nor could we judge with certainty
the presence or absence of pus within the veins. Failure to
find bacteria in the general circulation gave no absolute
assurance of the localized character of the infection,
nor could a physical examination of the lungs and other
viscera exclude the possible presence of metastatic focus.

3. It was in direct violence to our rules of practice to treat
infection before the infection was treated. What we might
have accomplished with those who would ligate the lower
end of the vena cava and both spermatic veins, stating
that the collateral circulation could be depended upon to
re-establish the return circulation. 4. The physical resist-
ance to retrograde operation was far below par, a fact
which made us cautious in adding further to their
burdens. We might well rob them of the little resistance
they possess. 6. Little dependence could be placed upon
serums and vaccines in these cases. 7. Whatever might be
our views on the question of the administration of a
safe and nourishing food. The Calcium Content of the Blood during Pregnancy, Labor, and the Puerperium.—Dr. W. H. Morley, of
Detroit, stated that calcium was a normal constituent of
the blood. Its function in promoting clotting of the
blood was explained. The determination of the amount
of calcium in the blood by chemical methods, and by the
gravimetric methods. Either of the two

methods mentioned required a large amount of blood in
order to lessen the proportion of error. The author de-
scribed a simple but accurate method of determining the
amount of calcium in the blood. The report of cases in which this method had been applied, and
stated what it had accomplished and what the knowledge of the calcium metabolism might show in the physiology and
pathology of pregnancy, labor, and the puerperium.

What are the Best Methods of Educating American
Women Concerning Cancer.—Dr. Frederick J. Taussig,
of St. Louis, Missouri, stated that it was almost impos-
able to have printed in a lay periodical intended for gen-
eral distribution any description so disastrous as the subject
of cancer of the uterus. The only way it could be done
was to incorporate it in a general article on cancer and
coached in special paragraphs referring to uterine can-
cer. Such words as cancer of the uterus could be
in an article so widely circulation thus obtained through some of our
women's magazines, he did not specially favor this method,
as its lack of directness tended to diminish its effective-
ness. He suggested an occasional article in the journals
of nursing, addressed to nurses, and contained a well-drawn
concise information as to early symptoms. Such
leaflet had better be given in person by the doctor, the
nurse, or the social worker. Leaflets that supplied the
information short of the fullest possible description, as
represented personally than if were send by mail. Much
could also be accomplished in his opinion through the
agency of women's clubs in the distribution of literature
and pamphlets. There was a directness in knowledge ac-
cquired by word of mouth that ordinarily made it better
retained. Hence he believed much could be accomplished
by lectures and personal conversation that mere printed matter failed to bring about. The lectures might be given either directly to the laity, before women’s clubs, or social settlement organizations, or they might be given to fore groups of such persons as would be most frequently called upon for advice, such as nurses, midwives, teachers, social workers, ministers, or druggists. He recommended that special stress be laid upon the early sympto- mens of various common diseases of the eye, and to all nurses’ training schools and all colleges of midwifery.

Report of the Committee on Ways and Means in the Matter of Impressing Physicians and Educating the Public in the Necessity of Early Diagnosis and Operation in Cancer.—This committee consisted of Dr. Howard C. Taylor, Dr. Frederick J. Taussig, and Dr. Leroy Brown, who reported that to accomplish this ends they were convinced that little could be done of lasting value excepting through an organized body, the sole purpose of which would be to conduct the needed campaign of education of scientific assistance and collection of data. They further believed that such a society should be of national scope, embracing all interested societies and organizations, together with lay people throughout America. The work of this society should be carried on by a competent paid executive secretary and his office corps, under the guidance of a central committee of surgeons to be appointed by its board of directors. The need of such a manner to be continued the possibility through its labors had been presented to certain public spirited women of New York city. Through their efforts and the hearty cooperation of the members of the American Gynecological Society, together with prominent surgeons and lay people, a meeting was held in New York city. At this meeting the present needs and status of the cancer problem were presented in full before them. At a later meeting of a committee on organization consisting of physicians appointed by this body the sum of $25,000 was guaranteed toward the expense of such a society for the first year. The committee was authorized not only to make a statement to the American Gynecological Society with this guarantee, but also to present the following resolution:

Resolved, That we request the American Gynecological Society to present the matter to each of the branches of the said congress interested in the subject and ask each of them to appoint a committee of two or more members to cooperate with them in forming a national organization for educational and publicity work regarding the recognition and treatment of cancer, and that they meet in such committees as soon as possible after the meeting of such congresses as such physicians and surgeons to be held during the week beginning May 4, 1913.

The committee recommended the endorsement and the enthusiastic cooperation of the society in the formation of such a national body. The committee further recommended that the American Gynecological Society appoint committees of two each to present this resolution to such component societies of the congress as they might deem interested in this matter, with a request for their cooperation. The resolution was adopted and the committee was appointed.

Officers.—The following officers were elected for the ensuing year: President, Dr. J. Whitridge Williams, Baltimore, Maryland; vice-presidents, Dr. Thomas J. Watkins, Chicago; Dr. C. T. Colton, New York city; secretary, Dr. Leroy Brown, New York city; reelected; treasurer, Dr. D. J. Wesley Boyce, Washington, D. C., reelected. Next place of meeting, Boston, Massachusetts.

Book Reviews.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as possible, we review those in which we think our readers are likely to be interested.]

The author has in this little book supplied the demands of the mother who wants to be intelligent in case of illness, and who is not satisfied to follow the methods advocated by her mother or grandmother. Of the many books of this kind which have lately appeared this is the most rational. The author rarely gives directions which are not based on previous skill or training, but indicates to the mother when a doctor should be called. The proprietary foods and condensed milk are rightly frowned upon for general use, and their proper indication is shown, i. e., for temporary use in illness or as adjuncts to modified milk. Several well selected illustrations make the text clearer. One is disappointed, however, after having the proper method of syringing the ear described, to find an illustration of a soft rubber ear syringe which is not alluded to in the text. The use of old linen in the same sentence with sterile gauze as a dressing for the cord is inappropriate in a modern book. The chapters on "Flies and Mosquitoes, When Should the Doctor be Sent For;" and "Vomiting in Newborn Infant; and Feeding;" are well written. Nor have the problems of the village, suburban, and country mother been forgotten. This is especially significant when we recollect that the death rate of many rural communities is higher than that of the cities. The little book will be found instructive not only to the mother but to the doctor himself.

The enlargement of the space of operations on the thoracic cavity may be produced by the introduction of methods of maintaining a difference of pressure has necessitated a complete revision of this well known work on the surgery of the lung. In its present form the book gives the reader a complete description of the surgery of this region as it exists to-day, and, coming from the pen of well known pioneers in this field, has a stamp of the highest authority. The work is admirably arranged, beginning with topographical anatomy, the pathology of pneumothorax, methods of maintaining a difference of pressure, and surgical technique, and finally passing on to injuries and diseases of the lung with their treatment. The chapter on the various methods of artificial change of intrathoracic pressure is particularly instructive. The authors take up in detail each form of apparatus, and afterwards give the advantages and disadvantages that have been found by actual experience to belong to each. Full credit is given the excellent work in this line that has been done by Willy, of Vienna, in his country. There is a good supply of plates and diagrams which help to elucidate this difficult branch of surgery. While primarily a book for the special workers in this field, it will be of great interest and value to the general surgeon and the physician who is not familiar with the progressive work that is being done in thoracic surgery and the new indications that are being laid down for interference in traumatic and pathological lesions of the lung.

The fourth volume of this important work on surgery deals with the surgical affections of the jaws, tongue, and alimentary canal and their treatment. So much progress has been made in the surgery of the stomach and intestines that the chapters devoted to them have been almost entirely revised in this new edition than any of the chapters of the preceding volumes. The result is that the book has been brought fully up to the times in the description of the
new diagnostic methods, indications for operations and operative methods relating to abdominal surgery. Some of the finer points in technic in which the American surgeons excel are found missing and furthermore one sees a desultory description of some method which has grown obsolete in this country. Thus the use of gauze packing for drainage in acute appendicitis has been discarded here in favor of rubber tissue. Furthermore the plan of leaving the rectus sheath open is adopted which is pointed out here to favor subsequent hernia. In general, however, operations advised and described are those which have stood the test of experience in Europe and America. The illustrations accompanying the description are excellent and admirably illustrate many of the points in technic. As a textbook for students the work should take a high rank on account of the excellent arrangement of the topics, its clear method of description, and its freedom from unnecessary interpolations of other methods or of procedure than those that have received the approval of the best authorities. The wise plan has been adhered to of giving full and detailed information as to the methods that have seemed best to the authors and reference only to others.

A considerable number of Americans live to-day with their families in our tropical possessions. This has come about from necessity and also because of the greater safety due to modern methods of sanitation. To look after the health of the young child has become an important part of the tropical practitioner's duty, and this work will prove of inestimable value to him. This will be true whether the physician has had a course in tropical medicine or not, for the handling of children in the tropics is an important branch of tropical medicine. The author has devoted himself to this subject and not touched upon by textbooks on diseases of children. The author is particularly fortunate in making his book interesting and valuable by his clearness of expression, avoidance of controversial ground, and particularly by his explicit directions as to treatment. Especially noteworthy are the chapters on "The Incidence of Disease in European Children in the Tropics" and the "Care of Infants in the Tropics." The pediatrician and the general practitioner of the country will greatly benefit by applying the principles outlined by the author to his summer problems in this country; of real value in this connection being the articles on humidity and effect of sunlight and diet. Malaria and dysentery, forming a large proportion of the children's diseases, are fully treated. We learn that in malaria the large mononuclear leukocytes are increased relatively to the other leukocytes, generally up to twenty per cent. and often more (the normal proportion being from five to ten per cent.). The author is a firm believer in the axiom "no anophelines mosquitoes, no malaria," and says that malaria is much more common, more severe, and more dangerous in young children than in adults, but more amenable to the action of quinine. We cannot agree with him in his ideas on feeding of infants, to whom he gives undiluted milk with sodium citrate, even when at birth they are below normal in weight. The little volume is well illustrated with well selected plates from larger works on tropical diseases. The book can be highly recommended, especially to the tropical physician, the pediatrician and the every physician practising in our southern States whose practice is among children.

The twenty-first volume of this important work by French authors is devoted to the surgery of the neck. The subject is condensed into a space of less than 200 pages which seems rather inadequate for such a very important topic. The first chapter deals with injuries. This is followed by a discussion of acute and chronic inflammatory lesions and their treatment. Tumors, cysts, fistule, and toricollis receive attention in the last chapters. The subject of goitre is not taken up in this volume. The articles are written by men of experience and the clinical aspects are kept uppermost. The discussion of such practical topics as the local treatment of enlarged glands from various causes, particularly tuberculosis, the pathology and treatment of the phlegmon and the differential diagnosis of certain tumors is very thorough and instructive. The text is clear, concise and free from the recital of personal experiences of specific cases. It is eminently fitted for the student and practitioner who wishes to get at the path of the subject without wading through unnecessary details. The illustrations are not in keeping with the good text. They are very sparse and not well executed. This is, however, a minor defect in comparison with the high order of the information to be obtained from the text.

Official News.

United States Public Health Service Intelligence:
Official list of changes of stations and duties of officers of the United States Public Health Service for the seven days ended July 16, 1913:

Draper, W. F., Assistant Surgeon. Directed to proceed to such places on the lower river as may be necessary in the conduct of the investigations of the pollution of the Potomac River.

Lavinder, C. H., Surgeon. Directed to report at Bureau for conference relative to plan and organization of pellagra investigation.

Vaughn, E. L., Acting Assistant Surgeon. Granted sixty days' leave of absence, without pay, from July 2, 1913.

Von Ezdorf, R. H., Surgeon. Directed to proceed to various points in the States of Alabama, Arkansas, Florida, Georgia, Louisiana, Mississippi, and South Carolina for conference with the State health authorities and for investigation of the prevalence of malaria.

Wickes, H. W., Surgeon. Granted one month's leave of absence from August 1, 1913.

Boards Convened.

Board of medical officers convened to meet Monday, July 14, 1913, at 10 o'clock A. M., at the Marine Hospital, New York, Md., for duty until August 30, 1913.

Lieutenant of Engineers F. E. Fitch to determine his physical fitness for promotion. Detail for the board: Senior Surgeon H. R. Carter, chairman; Passed Assistant Surgeon J. T. Burghhalter, recorder.

United States Army Intelligence:
Official list of changes of stations and duties of officers serving in the Medical Corps of the United States Army for the week ending July 19, 1913:

Armstrong, John M., Medical Reserve Corps. Ordered to active duty in the service of the United States on account of an existing emergency from July 14 to August 22, 1913. Lieutenant Armstrong will report on July 14th to the Commanding Officer, Fort Snelling, Minn., for duty until August 30, 1913. He will stand relieved from active duty in the United States Medical Reserve Corps.

Brechemin, Louis, Colonel. Upon being relieved from duty at the Medical Supply Depot, St. Louis, Mo., will proceed to New York city, and assume charge of the Medical Supply Depot of that city.

Brooke, Roger, Major, Retired. Returned to the General Hospital, July 7th, for leave of absence and detailed duty. Brooke, John D., Medical Reserve Corps. Ordered to active duty in the service of the United States on account of an existing emergency from July 10 to 30, 1913. Lieutenant Brooke will report to the Commanding Officer, Fort Meade, South Dakota, for duty until July 30, 1913, when he will stand relieved from active duty in the Medical Reserve Corps.

Buck, Carroll D., Major. Is relieved from further duty with
the Second Division, Texas City, Texas, and will proceed to Fort Mackenzie, Wyo., for the purpose of transferring public property for which he is accountable. Major Buck will stand relieved from duty at Fort Messina on July 24, and Major Delos will proceed to this property, and will then proceed to Washington Barracks, D. C., and report in person to the commanding officer of that post for duty and by letter to the commanding general, Eastern Department, relieving Major Charles H. Roberts, Medical Corps, who until now has been on duty at Genoa, Nev. In his absence, Crosby, W. D., Colonel, granted leave of absence for one month and fifteen days, about July 1st. Davis, William T., Captain. Is relieved from duty as assistant to the attending surgeon in Washington, and upon the expiration of the leave of absence herefore granted him, will proceed to Fort Leavenworth, Kansas, and report in person to the commanding officer of that post for duty and by letter to the commanding general, Southern Department. Cowles, G. D., Captain. Leaves Texas City on July 15th, after four months in that city. In his absence, Crosby, W. D., Colonel, granted leave of absence for one month and fifteen days, about July 1st.

**United States Navy Intelligence:**

Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Navy. Below reported duty in this column.

**Births, Marriages, and Deaths.**

**Married.**

**Wertenbaker.** In Washington, D. C., on Sunday, July 6th, Dr. C. I. Wertenbaker, aged thirty-nine years.

**A board of officers is appointed to meet at the call of the president thereof at Fort Monroe, Va., August 1, 1913, for the competitive examination of such enlisted men as may be ordered before it to determine their fitness for promotion to the grade of second lieutenants in the Coast Artillery Corps; the lieutenant of the transferee Major Powell C. Fauntleroy, Medical Corps; Captain Archibald H. Sunderland, Coast Artillery Corps; Captain William H. Smart, Medical Corps; First Lieutenant Robert Arthur, Coast Artillery Corps; First Lieutenant Alexander J. Smart, Coast Artillery Corps. The junior member of the examining board other than a medical officer will act as recorder.**
REPORT OF TWENTY CASES OF INFLAMMATORY AFFECTIONS OF THE LABYRINTH.

BY WENDELL C. PHILLIPS, M. D.,
EDMUND PRINCE FOWLER, M. D.,
SAMUEL J. KOPETZKY, M. D.,
AND J. CLARENCE SHARP, M. D.,
New York.

Introductory.

The following series of labyrinth cases have occurred in my service at the Manhattan Eye, Ear, and Throat Hospital, in my private practice, and in the private practice of those whose reports follow. It should be noted that the diagnosis and treatment of cases have been reported in full, but without comment or conclusions. In some of the earlier cases the labyrinthine tests were somewhat crude.

Report of Eight Cases.

By Wendell C. Phillips, M. D.

Case I. Miss M. P., aged twenty-seven years, consulted me on February 18, 1910, complaining of pain in the left ear, which had continued for several hours. There was a distinct bulging of the drum membrane, and a paracentesis was performed, under gas anesthesia. Two days later mastoid tenderness developed over the antrum and tip of the same ear, and I sent her to the Manhattan Eye, Ear, and Throat Hospital. The discharge was not profuse, and the house surgeon was directed to repeat the paracentesis. She gradually improved, and was discharged from the hospital on the 20th inst. Two days later she complained of slight headache over the left parietal region, and of severe and continuous vertigo. The ear was discharging slightly, but there was no mastoid tenderness. Her gait was extremely unsteady, with a tendency to fall toward the right side. There was no spontaneous nystagmus. There was no aerial hearing in the left ear, and no bone conduction on the left side, and when the fork was applied to the mastoid of the left side it was heard distinctly in the opposite ear. Upon rotation the left vestibular apparatus was not irritable. The vertigo remained severe and continuous, even when the patient was lying down. She was kept in bed in a dark room for nearly three weeks, during which time the aural discharge gradually disappeared and the vertigo subsided. She had absolutely no hearing in the affected ear when the noise producer was used on the opposite side. Upon rotation at this time a very slight reaction was obtained. On September 20th, of the same year, she returned for examination, when it was found that there had been no improvement either in the hearing or in the static labyrinth. She was not seen again until January 6, 1912. She has had no recurrence of discharge, but does complain at times of noises in the left ear. She is still absolutely deaf to all sounds, both aerial and by bone conduction. Upon rotation to the right she has an after nystagmus of ten seconds. Rotation to the left induces nystagmus of five seconds. She volunteered the statement that even at this time she is wholly unable to locate the direction of sound.

Case II. Sophie W., aged twenty-six years, married, housewife.

Previous history: Remembered no diseases of childhood. Had an abscess of the left ear when thirteen years of age. Since then there has been a discharge off and on. Sometimes the discharge was purulent, and at other times small, foul smelling pieces came from the ear. At intervals there was slight headache. Three weeks before coming to the clinic she had violent vertigo accompanied by nausea upon introducing the index finger into the left ear. Patient states that she had had milder vertiginous attacks before this.

Functional examination: Patient had spontaneous rotary nystagmus in both directions, in the extreme lateral positions of the eyes; more marked toward the diseased (left) side than toward the sound (right) side. Weber test referred to the sound side, and hearing totally lost in the diseased ear (left). Rinne test, with the bone and air apparatus. Rotation showed both labyrinths functioning; caloric test gave a decidedly prompt reaction; fistula test positive. Compression and aspiration gave typical reactions.

Operation, December 30, 1911: Mastoid abscess was discharged. Labyrinth removed. A large cholesteatoma occupied the attic, aditus, and antrum. A defect in the bony wall of the external semicircular canal was found; this admitted a probe which passed out of the oval window. After the operation she had a rotatory nystagmus toward the sound side in all positions of the eyes. There were, however, no disturbances in equilibrium. She could lie on her back with comfort and was never compelled to lie on her sound side. No vomiting; temperature normal.

Case III. Male, aged about twenty-eight years, was referred to me at the Manhattan Eye and Ear Hospital, March 2, 1912, giving the following history: He had had suppuration in the right ear for a period of five months, with no complicating symptoms of any nature up to three days before coming under observation. Two days previously he had been seized with an attack of vomiting and dizziness, the latter of which had remained continuously. He had no rise of temperature, and did not complain of pain in the mastoid, nor was there any tenderness upon pressure. He was totally deaf in the right ear. The caloric reaction was negative in the right ear, but positive in the left. He had spontaneous rotatory nystagmus to the left. When walking he was inclined to fall toward the right. He was immediately admitted to the hospital, and the radical mastoid operation was performed. The mastoid antrum and cells contained a small amount of pus, and there was much granulation tissue in the tympanic cavity. There was no fistula of the labyrinthine capsule, but the region of the round and oval windows was granu- lated. He was banded to the probe. The patient made a good recovery from the ether and passed a good night; was rational and answered questions early the following morning.
Later in the morning he began to show signs of meningeal irritation, with a moderate rise of temperature. At noon of the same day there was a sudden rise of temperature to 101.8°, and the blood pressure had increased to 240, apparently of respiratory failure. At the time of operation the eye grounds were examined and found clear. A specimen of cerebrospinal fluid was also removed at the operation and did not show signs of meningitis. X-ray examination to the brain, according to Kopetzky. Immediately after death lumbar puncture was made; the fluid was cloudy and gave abundant evidence of meningitis.

Case VI. F. W., male, aged eighteen years, consulted me on April 2, 1912, with the following history: On January 2, 1912, he had suffered from an attack of mumps of extreme severity. During the early stage he had fainting spells and his family physician had told his mother that the pancreas was evidently involved. Two weeks from the onset of the attack he became extremely dizzy and complained of excessive tinnitus in the right ear. Three days later he became completely deaf in the right ear, and his family physician stated that the eyes were slightly fixed toward the right side. For four days during this time he was almost entirely unconscious; the vertigo remained severe, and continued for over two weeks. During the four severest days forced feeding became necessary. The vertigo was not improved by activity, and the vertigo finally disappeared, but his hearing remained nil. A sister contracted the disease from him and her attack was followed by a double ovaritis, and for a period of one week she had double vision. At another examination the patient had entirely lost the hearing in his right ear, both air and bone conduction being destroyed, as proved by the employment of the noise producer. The semicircular canals had evidently somewhat improved, but the nystagmus upon irrigation of the right side had not less than 3° of the sac on the left side. He was examined on January 4, 1913. He is still completely deaf to all sound, but the vestibule upon the affected side is now irritable.

Case VII. C. A., aged twenty years, laborer. Family history: Father, mother and two sisters died of tuberculosis.

Personal history: Does not remember any diseases of childhood. Has always been well as far as he knows. Left ear has always been normal. The right ear began to ache and discharge about fifteen years ago. At that time he had a simple mastoid operation performed, and the posterior wound had never healed. The ear had continued to discharge ever since. He had no pain in the ear, however, and no discharge, which was remarkable. A swelling appeared behind the right ear. He never had any vertiginous attacks; nor had he had attacks of nausea and vomiting.

Functional tests: Functional tests showed total destruction of both cochlear and labyrinthine function.

Operation: Incision through the old cicatrix. Cortex dense and the mastoid sclerosed; antrum small and filled with cholesteatoma. Middle ear filled with granulations and cholesteatoma; promontory apparently sound. Large irregularly shaped fistula in the horizontal semicircular canal, about one quarter inch long. The canal looked like a curious tooth whose crown had been crooked. A probe passing through the canal passed into the oval window. The vestibule was not opened further.

Facial paralysis followed the operation. Flap made about ten days later. Wound not fully healed. At present inner tympanic wall covered with granulations.

Intracranial tests show total destruction of both cochlear and labyrinthine function.

Case VI. Mrs. E. C., about thirty years of age, married. I saw this patient for the first time at her home on January 11, 1912, in the presence of her husband.

The right ear had discharged since childhood, with varying intervals of cessation. For five weeks there had been considerable discharge of dark colored odorous pus. Five days previous to the above mentioned date she began to have vertigo and became unable to stand up. Vertigo had increased in severity and frequency. The vertigo was extreme and she complained of slight parietal headache on the affected side. She had slight spontaneous nystagmus to the right on extreme abduction. Both vestibules were irritable, and she had a slight degree of hearing upon the affected side. No caloric test was made. Radical mastoid operation was performed on June 10th, at which time a fistula of the external semicircular canal was found. A large amount of pus and some mass of cholesteatomatous material. Recovery was slow, partially on account of the patient's lowered vitality, and she had slight attacks of vertigo at long intervals for several months. At the present time the wound is entirely healed. She had a slight hearing, and her vestibule is irritable upon rotation.

Case VII. A Greek, twenty-five years of age, came to my clinic at the Post-Graduate Hospital on March 19, 1912. He was an unusual case for two reasons: he had vitality. Had complained of acute pain in the left ear for about four weeks, but no discharge took place until one week previous to admission, when a paracentesis was made by a physician whom he had consulted. When he consulted me, one week after the paracentesis, he was extremely dizzy and had a severe profuse discharge from the left middle ear. He had extreme mastoid tenderness and a large postauricular swelling over and below the tip. In other words, his was a case of so called Bezold mastoiditis. His hearing was entirely gone in the left ear, and the canals of that side did not respond in any manner either to the rotation or the caloric tests. He had a spontaneous rotatory nystagmus to the right. He made no complaint of vertigo. He had attacks of hearing, but he had extreme vertigo and staggered when walking, but did not fall typically away from the nystagmus direction. Was admitted to the hospital for observation. The next day he complained of slight headache, but was otherwise entirely comfortable. The impression was made that the same, with the exception that he had a temperature of 102.5° F. Cerebrospinal fluid drawn at one o'clock that day was hazy and contained pus cells. Culture of this fluid afterwards showed streptococcus infection. The patient had no complaint of headache and did not seem particularly ill.

The same afternoon I performed the radical mastoid and the Neumann labyrinthine operations. He had an unusually large pneumatic mastoid process, the cells being highly pneumatized, and the meninges hyperemic. No fistula was found. Following the labyrinthine operation it was determined, if possible, to anticipate the dangers of intracranial pressure by draining the cisterna magna. This operation was performed by Doctor Kopetzky, and free drainage of cerebrospinal fluid was obtained. The clinical picture afforded by the subsequent history of the case is well worthy of observation.

The following day the temperature remained entirely normal and the patient's general condition was excellent. Mentality was entirely normal, and he was cheerful. On the 23d he had a considerable rise of temperature, at one time reaching 104° F., but the pulse was 88. He still seemed entirely comfortable. His nystagmus to the right side was still present, and his vertigo did not improve. Blood culture made that day showed no growth. He was not restless and his mentality was normal. In fact, no symptom of meningitis was present excepting the rise in temperature. At one time during the following two or three days the opening into the dura became blocked, and for a short time he was slightly somnolent. This was entirely relieved upon the reestablishment of drainage. Conditions remained practically the same for nine days when the temperature began to fall. The temperature was high, around 103° to 104° F., until the eighth day, when it became more septic in character, ranging from 97° to 103° F. Even at this time the patient remained entirely comfortable, and was able to go up and down the ward. On the day in the 28th he was asked for a glass of water, and suddenly fell backward into bed and died.

Case VIII. Mrs. B., aged seventy-one years, was brought to me by her family physician, from a distant town, December 1912. She had been a traveling nurse. She stated that she had been deaf in the left ear for fifteen years, during which time she had had spells of dizziness, but to the best of her knowledge she had had no discharge from this ear until one year ago, when a discharge began in the left ear, for which she has gone to special causes for special pains or suffering. Of late the pain in her left ear and mastoid region had been severe and the discharge had been both profuse and offensive. While she states that she had had dizzy spells for two years, her vertigo began to be severe just one month ago, and at about the
same time she began to have more pain in the mastoid region, and more discharge. She had had a few attacks of nausea and vomiting.

On examination of the middle ear there was found a perforation superficially and posteriorly, through which discharge was coming, and I thought I saw indications of cholesteatoma in the antrum or mastoid. The patient had slight hearing for the voice, and she could hear tuning forks placed on the left mastoid, but referred the Valsalva to the right middle ear. She complained of nausea and vertigo, and was unable to sleep except for a few minutes. She had slight nausea and vertigo to the left; lasting twenty-five seconds. There was no spontaneous nystagmus. The patient reported any incoodination to be in the nature of a rightwards nystagmus, which occurred three to four per day. She said the same. The fistula test was positive, producing a horizontal nystagmus to the left; the caloric test was not tried.

The radical mastoid operation was performed. The surgeon himself performed the operation, and this was done in an ordinary way. Wound and operation were free from all complications.

She was discharged from the hospital on the seventh day after discharge from the ear, with the mastoidectomy cast. During the first week after discharge from the hospital, she was reported to have had no discharge from the mastoid wound, and no vertigo.

On October 18th a secondary operation was decided upon. This was to be performed in order to test the antrum. The patient was discharged from the hospital on October 27th. On November 1st she was discharged from the hospital with the following report:

"The patient was discharged from the hospital on November 1st. She was free from all complaints, and was able to go about her usual duties. She stated that she had no discharge from the mastoid wound, and that she was free from vertigo. She was able to hear the voice and tuning forks. She stated that she had no vertigo, and that she was able to sleep without difficulty. She was discharged from the hospital on November 1st.

"The patient was discharged from the hospital on November 1st. She was free from all complaints, and was able to go about her usual duties. She stated that she had no discharge from the mastoid wound, and no vertigo. She was able to hear the voice and tuning forks. She stated that she had no vertigo, and that she was able to sleep without difficulty. She was discharged from the hospital on November 1st."
stagnus at any time. No facial paralysis followed the operation.

About two months later a radical operation was performed upon the opposite ear to forestall a fate similar to its fellow, and the wound has healed slowly. At the present time there is still some discharging from both ears. He has no hearing in the left ear. Rotation to right or left elicits no nystagmus until ten turns are made in ten seconds, when it is found that rotation to the right produces slight nystagmus. The test of three seconds' duration. Hearing for loud voice present in the right ear which lately has improved markedly in function and in wound appearance.

Case IV. C. F., aged thirty-one years. No history of disease of the ears. The patient complained of a dull attack of grip. She developed an abscess in the left ear two and a half months ago and suffered severe pain in this ear for two days. She complained of deafness and a pounding tinnitus. For the past two weeks she has had a severe vertigo, and on one occasion fell to the floor while leaning forward. She has also had six or seven attacks of nausea and vomiting during this period. Upon examination, the right ear appeared normal. There is much tenderness in the left ear, but it is not tender when my noise producer is used in the opposite ear. She has a spontaneous nystagmus to the right and the caloric test is negative. The fistula test in the left ear gives a very marked response, with a nystagmus to the left. When the patient is tilted forward she makes some nystagmus as though she were falling forward; when her head is tilted backward she feels as though she were falling backward. When a constricting band is placed about the neck, the spontaneous nystagmus and vertigo are diminished, and nystagmus to the left becomes the dominant test by the caloric and fistula tests. (This is my method of differentiating between suppurative and nonsuppurative labyrinthitis.) The mastoid is quite tender upon firm pressure especially over the emissary vein. Operation showed chronic condition of mastoid and mastoidectomy of the tip, where a pocket of pus was discovered. The inner table over the lower third of the lateral sinus was necrotic. In the antrum pus and granulations were found. The tegmen was necrotic and the drum was exposed. The bony semicircular canals were freely exposed, but no fistula was found. She made an uneventful recovery without having a temperature over 100°F. Vertigo and nystagmus were absent immediately following the operation.

Fistula test negative three months after operation. As the region was tender, I used one of my massage cups to accomplish the compression. Tinnitus was like the sound of seashells. She has never felt better and has gained fifteen pounds in weight. Patient discharged January 6, 1913; Hears the whisper in the right ear thirty feet; in the left ear, eleven feet. Ear dry for two months, and a recent severe attack of scarlatina has failed to involve either ear.

Report of Three Cases.

BY SAMUEL J. KOPETZKY, M. D.

Case I. Following a submucous resection of the nasal septum, Mr. D. L. came under my care at the New York Red Cross Hospital on January 15, 1910, suffering from an acute mastoiditis on the left side, and an acute otitis media purulenta on the right side. The simple mastoid operation was performed on the left side, and the right placed under local treatment. Patient discharged February 10.

On May 31, 1910, the right mastoid gave classical symptoms, and the patient underwent a simple mastoid operation at the Red Cross Hospital, being discharged therefrom on June 22, 1910. He was discharged from the South, where the aftertreatments were carried out. On August 29, 1910, he was again brought to New York suffering with an intense headache, which had lasted for ten days, most intense over the mastoid area on the right side, and radiating from behind and below. The pain was not controlled by drugs. The wound was still discharging, and the middle ear was not dry.

Condition on admission: The right mastoid wound showed a deformed scar with a persistent mastoidal opening one half inch in diameter. The middle ear was also discharging pus. The caloric reaction was negative on the right side. Patient also was deaf for voice and whistles on the right side. Radical mastoid operation performed August 29, 1910. Bone found infiltrated with pus. The sinus and dura over tegmen exposed and examined, and found to be normal. Labyrinthine wall searched, but no lesion found. Periostal flap. September 1, 1910. Spontaneous nystagmus present (note of its character given). Has vertigo and nausea. When patient is turned upon his right side the sensation of vertigo is intensified, and when eyes are fixed upon a point, oscilatory nystagmus toward diseased side is apparent. The pressure test is not impaired on the opposite side. Temperature, 102°F. Patient placed in a darkened room, head immobilized, the eyes bandaged, and ordered kept absolutely quiet. September 4, 1910. Spontaneous nystagmus has disappeared. Patient kept quiet in his bed during the week; the vertigo and nausea being being once, apparently healing properly. Left New York in December with wound in middle ear almost epidemized. Some granulations on the promontory, from which secretions came away. Patient still deaf in the ear, although exact data on tests are lacking.

He reappeared in New York July 14, 1911. Examination showed a radical wound cavity almost completely epidemized, some granulation on the promontory, and a moderate amount of discharge from ear. Patient is able to hear voice; laterizes to the right, and does not hear through air conduction, although heard through bone conduction. C fork heard in this ear. Lower tone limit at or above 64 D. V. July 23, 1912. Reexamined. Still shows granulations, especially in the wound. Discharge can be seen coming away. Patient complains that he has lost the sensation of the direction from which sound comes. Laterizes toward this ear: C not heard through air, but heard through bone. 512 D. V. heard through air, with noise apparatus. C, C, C, D. V. heard in opposite ear. Has occasional spells of dizziness, especially when suddenly changing the position of the head, as when bending down or when raising the head. Caloric reaction now positive in this ear.

Diagnosis, ossicular fistula. Convexity of middle ear, circumscribed labyrinthitis. Rest cure; recovery with postoperative sequestra formation, which I think he will eventually throw out spontaneously. Patient attending to his business.

Case II. Mr. F. C., aged thirty-nine years, came under observation September 23, 1912. Ten weeks ago, following sea bathing, had an attack of acute otitis media purulenta, which was treated by family physician, by paracentesis, and douching. Removed from his office a week previous to his appearance at my office he suffered with a severe pain in the right ear; on the last day he complained of chilly sensations. On the morning of September 23d he woke up to find the right side of his face paralyzed, and that he was unable to walk without staggering.

Examination: Classical signs of acute mastoiditis with facial paralysis, involving all branches of the nerve; upper branches less markedly involved than the others. Patient staggered toward opposite side when walking; spontaneous horizontal nystagmus present. Hearing absent with noise apparatus in the opposite ear. Caloric reaction absent after three minutes trial in the right ear; present after thirty seconds in the normal ear.

Radical mastoid operation at Red Cross Hospital, September 23, 1912. Periostal abscess uncovered; no lesion found in labyrinthine wall; no exposure of the facial nerve noted. Pus evacuated between sinus wall and posterior mastoid wall near bulb. All symptoms abated within a week; Patient discharged October 1, 1912. Uneventful recovery thereafter.

Examined December 10, 1912. Lateralizes toward the right side (affected ear).

C fork heard 20/20 of normal through air.
C fork heard 20/30 of normal through bone.
C fork heard 22/60 of normal through air.
512 D. V. heard in the ear.
64 D. V. not heard in the ear.

Case III. Miss C. L., aged twenty-one years. Admitted to Doctor Phillips's service in the Manhattan Eye, Ear, and Throat Hospital, November 10, 1912, suffering with recurrent mastoiditis, for which a radical mastoid opera-
tion was performed November 16, 1912, with the usual findings. November 18th, 2 a.m. Patient complains of extreme deafness, and has attack of persistent vomiting. November 18th. Dizziness continues; spontaneous nystagmus present. No rise in temperature. Eyes masked and quiet ordered.

December 1. Lateralizes to healthy ear: No hearing for C fork with noise apparatus in opposite ear. No hearing for C fork or voice and whistle heard with noise apparatus in opposite ear.

November 28th. An attack of extreme dizziness. November 30th. Headache noted—ice cap applied. December 20th. Complains of dizziness following quick motions. December 28th. Tests as follows:

Turning test: To right to X after nystagmus to left—0. To left to X after nystagmus to right—16 seconds.

Caloric reaction—cold water Rt—1 minute 50—positive reaction. Left ear—2 minutes 50—no reaction.

Voice, whistle and forks, with noise apparatus in opposite ear—total deafness in left ear. Patient complains of some tinnitus in the left ear; ear not yet dry; epidermalization incomplete. Diagnosis, acute serious labyrinthitis or acute purulent labyrinthitis.

January 7, 1913. Ear shows slight discharge.

Report of Five Cases.

By J. CLARENCE SHARP, M. D.

CASE I. L. S., aged twenty-seven years, consulted me on January 12, 1911, complaining of tinnitus dating from October 1st. On November 4th he had an attack of vertigo which was soon followed by a complete facial paralysis. Complained of slurred headaches during the attacks of vertigo; never had discharge from the right ear; drum membrane dark red in color, but with no bulging. Functional tests: Caloric negative; no hearing, even with the noise producer. Turning tests: When turned to the right, no after nystagmus follows; turning to the left produced after nystagmus for thirty seconds.

Patient denied any history of syphilis, but the Wassermann test was strongly positive. He was placed on antisiphilitic treatment and began to improve after fifteen days. The improvement continued with the exception that the loss of hearing remained permanent. On January 4, 1913, the galvanic test, applied to the left ear, showed nystagmus to the left with six millione primarily; galvanic test, applied to right ear, showed no nystagmus to the right with 750 milliamperes.

CASE II. Miss M. D. H., aged thirty-five years, was referred to me May 11, 1912. She gave the following history: When eleven months old had scarlet fever; at this time had abscess in left ear, which discharged for some time. Tinnitus began at this time and her seventeenth year she remembers two (2) different periods when her ear discharged, and this always began without any preceding pain. The discharge was never profuse and probably lasted not longer than ten days or two weeks. When seventeen years of age she had measles, and again the ear discharged about two weeks. From this time on, for a period of eighteen years, she had had no trouble until last April (1911), when the ear began, without any pain, to discharge, and has continued to do so ever since. The first of May, 1911, granulations formed, which were catarterized; she had no further treatment except the inflation of powder into the ear. One year later, Wednesday, May 8, 1912, she complained of pain in the left ear, this continued, and the following day it began to discharge freely. Friday morning she noticed that her face was drawn a little to the right. This increased, and by the following morning she had a complete facial paralysis.

Examination: Right ear normal. Left ear, no swelling over mastoid, but pain on pressure; external auditory canal full of pus; large perforation in drum, surrounded by granulations. Functional tests: Caloric reaction negative; no hearing in the left ear when the noise producer was used.

Patient was operated upon the same evening: the antrum was filled with cholesteatomata. The mastoid cells, including the tip, were removed because of the granulations. After removing the posterior meatal wall, the tympanic cavity was found full of cholesteatomata.

After these were removed, and the cavity was enlarged, the facial canal was found intact; part of the incus and malleus was present. Upon touching the promontory, it came away, showing the cochlea filled with granulations. Upon clearing this away, the jugular bulb could be seen. The inner tympanum wall was soft and covered with granulations; the vestibule was also full of granulations. The Eustachian tube was curetted and enlarged; no fistula could be seen in any of the canals. (See illustration.) After making the flap, the posterior wall was closed. The face began to show improvement by the fourth day, and at the end of the third week the paralysis had cleared up. She made a good recovery and, by November 1st the cavity was dry. She complains of being dizzy once in a while, but this is gradually growing less. Functional tests still negative.

CASE III. M. S., male, aged twenty-two years, was admitted to the service of Doctor Phillips at the Manhattan Eye, Ear, and Throat Hospital, June 15, 1912, with the following history: He had an abscess in his left ear five years ago, which healed without any treatment. June 1, 1912, the same ear began to discharge again, but gave him no pain. The discharge increased and he came to the hospital for relief. Examination showed that the canal was full of pus, with perforation in the posterior and inferior portions of the drum membrane. No pain or tenderness over the mastoid process, and no dizziness. The discharge lessened after two or three visits, and he did not return until June 28, when he complained of being very dizzy; was afraid to walk on the street alone or go up and down stairs. He had a tendency to fall to the right side, and held his head to the right. Examination showed his ear still discharging, with marked tenderness over the mastoid. Ear tests showed no functional activity either of the cochlea or the vestibule. Diagnosis of labyrinthine disease was made and immediate operation advised, which he refused. Did not return until July 2d. On this date he had increased tenderness over the mastoid and greater difficulty in walking, and was in so much distress of mind that he agreed to be operated upon at once. He was admitted to the hospital and was operated upon the same
afternoon. Upon removing the cortex, the sinus was found very far forward, close to the posterior wall. The antrum was full of cholesteatoma, and, upon clearing this away, the three semicircular canals were exposed, but no fistula could be found. Removal of the posterior wall showed the tympanic cavity also full of cholesteatoma. After clearing these away, the facial canal, as it entered the periotic, was found necrosed, exposing the tympanic cavity. The stapes was found covered in a mass of granulations, and the inner tympanic wall was also found covered with granulations; cochlea intact. Facial paralysis developed the following day, but is now beginning to clear up. I wrote my case was healed, leaving him in charge of Doctor Friesner, who reports that for several weeks he would become dizzy when the wound was dressed, showing that he must have had some irritation left in the vestibule. He made a good recovery; the cavity was dry by October 8th.

December 27th. Tests show no functional activity of the cochlea; turning to the right, nystagmus nine seconds; to the left, fifteen seconds. This does not show complete compensation. December 28th. On turning, shows practically no nystagmus of either side, but this symptom varies from day to day. January 4th. Galvanic tests show rotatory nystagmus, to the left, with one milliamperc; rotatory nystagmus to the right with 1/2 milliamperc.

Case IV. Mrs. F. F., aged fifty-five years, was admitted to the service of Doctor Phillips at the Manhattan Eye, Ear, and Throat Hospital, June 23, 1912, with the following history: During the time of her first confinement, at the age of twenty-one, her right ear began to discharge. This continued for some time, it was treated off and on, and gradually dried up. Later it discharged for a day or so, and then would stop. On July 9, 1912, she was awakened in the morning by a severe pain in her right ear, which later began to discharge. She paid no attention to it but ten days afterward she noticed that she could not move the muscles of her face, very well on the right side. This gradually grew worse and she came to the Manhattan Eye, Ear, and Throat Hospital on July 12th. On examination, showed complete facial paralysis on the right side; the external auditory canal was filled with thick pus. Functional tests: Caloric tests show no reaction; no nystagmus upon turning; no hearing in the right ear upon use of the noise producer. The radical mastoid operation was deemed necessary. The antrum and tympanic cavity were found filled with cholesteatoma. They had destroyed the roof of the antrum, exposing the dura of the middle fossa; also most of the posterior wall. On cleaning away the debris, all the semicircular canals were found covered with fistulae, walled off in the horizontal semicircular canal. I then opened into the vestibule, so that a probe could be passed out through the oval window. The facial ridge was necrosed; the inner tympanic wall was covered with granulations and was not intact. The mastoid process was carelessly treated. After making the flap, the wound was closed. She made a good recovery, the cavity being dry by October 15th.

November 30th. The paralysis is much improved; she is able to nearly close the eye, and can move the muscles about the corner of the mouth. Functional tests show no caloric reaction; no hearing; turning to the right, nystagmus thirty seconds; turning to the left, twenty seconds, shouldering compensation for the labyrinthine system. Case V. J. A. G., aged twenty-one years, was admitted to the service of Doctor Phillips at the Manhattan Eye, Ear, and Throat Hospital July 6, 1912, with the following history. Left ear was discharged since childhood; it was discharging for three or four weeks; and then not again for three or four months. About four years ago, he began to get dizzy. For the past four months the ear has discharged profusely, but given him no pain. He was unable to take any work that required him to lean over, as he always became dizzy and would fall to the right. During all these years, he has had only two months' treatment. Examination showed complete destruction of the drum membrane; cholesteatoma can be seen in the tympanic cavity; mastoid very tender; hearing loss; temperature by mouth, 101° F. Functional tests show caloric reaction present; can hear whisper twenty feet; turning shows nystagmus; fistula test gives horizontal nystagmus, showing that has a fistula of his horizontal semicircular canal. He was operated upon at once. The antrum was found full of cholesteatoma. Upon clearing away this mass, the horizontal semicircular canal was exposed, showing a fistula. The membranous labyrinth, or what appeared to be this, could be seen very plainly. After removal of the posterior wall, and clearing the tympanic cavity of the cholesteatoma, the stapes was found hidden from view in a mass of granulations, and was not disturbed. After making the flap, the wound was closed posteriorly and the patient made a satisfactory recovery. On December 8th I had a note from him, reporting that his ear was dry, but he still had some ringing and dizziness. 40 West Forty-seventh Street.

PELLAGRA, SURGERY, THE COLLOIDS, AND STRONG DRUGS;
Also Introducing a Possible New Etiological Factor.*

By HARLAN SHOEMAKER, A. B., M. D.,
Surgeon, Shelby Hospital.

Situated in an isolated and rural community, it has been possible for me to see a number of cases of pellagra develop from the very incipency of a gastrointestinal disturbance to a profound pellagous explosion. These cases have shown every variation of the disease in its course, development, and termination.

In 1910 there were known to me about ten cases of pellagra in Cleveland County; in 1911 I could easily figure up fifty; in 1912, a hundred; and this year the incidence of this disease is almost that of measles. As these cases have terminated in a variety of ways, and as some of the methods used in their treatment are even more varied, I introduce them to you, hoping that without further confusing you I can suggest a possible new factor in the etiology of this disease and a rational explanation of the uniform results obtained by so many divergent means of treatment.

First, let me say that this paper is no statistical study of pellagra, but purports to convey the prevailing idea obtained by me through a careful study of the case at hand. Some of my points I shall try to verify to your satisfaction out of my own experience and from that of others. I realize that the views set forth are so divergent from the accepted teaching that I may seem contentious, but those familiar with this subject know that pellagra was first thought to be a disease produced by infected corn and of nervous origin—observe the vast amount of literature on the nervous phenomena of this disease by the great nerve specialists. Next it became a gastrointestinal intoxication, and last an infectious disease produced by a parasitic host with its attending phenomena. To begin at the end, my cases have terminated as follows: Some have recovered through the hypodermatic administration of strong drugs; some have recovered by a variety of operations; and some have recovered spontaneously; some have died, though I am happy to state that all of the operative cases, including two patients who went insane, have recovered and escaped pellagous symptoms one season.

*Read before the North Carolina State Medical Society, June, 1913.
What fundamental condition could cover such a variety of procedures? The office case histories of indigestion in 1910 proved to be the pellagrous infections of 1911. The symptoms of 1910 were mild epigastric disturbances of digestion, accompanied by small aphthous patches on the tongue and buccal mucous membrane, excepting that over the alveolar processes, and some numbness and tingling of the hands and feet. Hypoleucytosis and a slight loss of weight are frequently added to this symptom complex. This loss has amounted to one quarter to one third of the body weight between Christmas and the month of May. As I have said elsewhere, when the rash appears a countryman can correctly diagnosticate pellagra. Inasmuch as the early diagnosis of this disease means so much toward the success of the doctor and the recovery of the patient, too much stress cannot be laid upon these symptoms when found to persist over some weeks. Diet and medicinal treatment are most efficacious at this stage, and all suspects should be put upon a proper diet and medication at this time.

During the year 1910 all the pellagra patients seen by me either lived at or had communication with Earl, N. C., a very small hamlet eight miles south of Shelby. Some of these patients were six miles west and twelve miles east of Shelby, but all gave a voluntary history of contact with pellagra cases at Earl. This suggested a contagious nature of the disease, and also suggested a fly belt at Earl. Since then, the spread of pellagra through the Piedmont section has been so rapid that all lines of contact are lost. While on a trip to the Pacific Coast during the winter of 1912, I stopped thirty-six hours in a city of 50,000 in northwest Iowa. There I saw two cases of pellagra, and was not in consultation with any of the profession. A subsequent newspaper clipping tells me that they have awakened. Two cases were shown to the county medical society of San Francisco. Pellagra is scarcely a problem of the South; it is national in scope. To my mind the general distribution of pellagra should discourage that element of the profession which chooses to act as medical director, telling the patient which climate to choose and where to find it. Disease should be treated at home. There lie all the economical and social advantages.

Much has been done along certain lines, especially by the neurologists on the pathology of pellagra; though, on the other hand, almost nothing has been done toward the pathology of the early symptoms. I have deliberately opened the upper abdomen in two early cases of pellagra for the purpose of draining the gallbladder, and I was fortunately able to remove the appendix through this high incision. The head of the pancreas was firm and thicker than the body. A number of edematous lymph nodes were easily seen and felt. The biliary fistula drained dark colored bile for six days in both cases, when the flow became characteristically greenish yellow. Drainage was removed on the tenth day. The patients were discharged from the hospital on the twenty-first day. One, a male patient, had an uneventful recovery; the other, a female, became pregnant, and nearly lost her life from recurring intestinal symptoms. The pregnancy ended in an abortion, and she is just now recovering her normal weight. Both patients had a hypoleucytosis. The condition found in the lymphatics in these two cases agrees with the autopsy findings in four cases reported by H. P. Mills.

Wood writes that the pancreas is not reported affected in pellagra, and I have not been able to find any reference to this particular gland, nor to any other of the deep structures of the upper abdomen, such as the great plexus of nerves below the pylorus, or even the receptaculum chyli, being affected. Still, pellagrins complain of distress in the upper abdomen from six to nine months before they really dispense with the diagnostic ability of the physician. When the pellagrions explosion occurs, and all the pathognomonic symptoms are lined up like a row of ten pins, one can feel beneath the buccal mucus membranes along the lower border of the inferior maxilla, especially if the submental tissues are supported by the free hand, a chain of lymph glands. Moreover, all authors agree that there is an increased flow of the submaxillary and sublingual glands. Would it not be fair to suppose that an analogous condition possibly exists in the pancreas when the descending duodenum is affected? Many authors speak of a characteristic odor of the stools in pellagra. It can easily duplicate the odor in vitro. Mince finely some pancreatic tissue from the dog and allow it to stand in an open beaker. When fermentation is well advanced, the typical odor of a pellagra stool will be obtained. Pellagrins do well on a high protein diet. Would not this factor suggest an altered function of the pancreas? Ferments or fermentable foods annoy the pellagrin; might not this suggest an alteration of the principal digestive ferments?

One more fact along this line, taken from Niles's book on pellagra, before I leave the most interesting phase of the subject to the surgeons. On page 90 Niles writes:

In one instance the writer had the opportunity of examining the duodenal contents of a pellagrin. The contents were obtained by the Einhorn duodenal bucket which was withdrawn ten hours after swallowing. The contents were golden yellow, thick, and turbid, and showing no action for trypsin. This, of course, proves nothing, being mentioned only as a matter of interest.

Again, on page 125, he says:

One of the most difficult complications to manage is the condition of marasmus or wasting away, into which the pellagrin sometimes lapses. A liberal diet seems to aid not at all, and emaciation rapidly supervenes, bringing with it apathy, mutism, lessened tendon reflexes, and muscular rigidity.

Now let us recall the six to nine months gastrointestinal disturbances and the high protein diet. If one of the three most important digestive ferments were destroyed in your patient, and the patient in turn lost about one third of his body weight in five months, what would you think? The chemistry of the descending duodenum must be variously disturbed in pellagra, because the diet which the individual pellagrins finds suitable to his economy has not yet been completely described.

Any attempt to introduce a new factor in the etiology of pellagra, unless it can be absolutely
proved to be of its true etiology, must necessarily add to the confusion that already exists. However, the suggestions put forth are necessarily forced upon us because of the tendency of one school of thought to accept the fly theory of pellagraous infection. My wife ventured the suggestion last year that the common fly would be found a carrier of pellagra. Jennings and King think from their survey that the stable fly (Stomoxys calcitrans) is the possible carrier and the common house fly (Musca domestica) may be a mechanical carrier. They fail to find the "jigger" (Sarcopsylla penetrans) and do not mention the common biting mite which people call "jiggers." Riley says in reference to jiggers:

The two mites described below cause great annoyance from harvest time till into October to people who frequent the rank herbage and grass in our forest openings or along our rivers. Both of them are 6 legged red dish microscopic species and both of them are popularly termed in the United States "jiggers." The term is evidently a corruption of "chigoe," the name universally applied to the more dangerous Sarcopsylla penetrans (sand flea), which will be described later, and the term "harvest mites" is preferable.

In some sections of the Piedmont "red bugs" is a popular term.

Dogs, cats, etc., from their prowling habits in field and garden suffer greatly and they scratch and nip their skin with their teeth, so much so that they are sometimes supposed to be suffering from the itch when it is only a reinforcement of the mites. They do not all deposit eggs in the wound they make, and soon die victims to their sanguinary appetite.

Nathan Banks writes: "To the ordinary person mites do not exist. Occasionally he may have painful evidence of their presence, but he has no idea of the number of specimens and species around him."

I removed from my clothes the second simulium of the season, March 25, 1913, and a short time prior to this saw the first one of the season. Shelby has been deluged with them this season. About the middle of March, while counting blood, I impaled a female house fly, fat and pregnant. On her ventral side I saw two mites, and a week later found one in a fly egg. To me this was a great discovery, but I soon found that the government expert in mites (acarica) had made it ancient history. My mite corresponds to the species "Leptus americanus" (Riley), and is the predaceous six legged parasite of the genus Trombidium (eight legged); order, Acarina; class, arachnida. This predaceous mite (Leptus americanus) moults several times before it becomes the adult "red bug," visible to the naked eye. There are other "red bugs" common to this vicinity, but they are not parasitic on flies (Acarina gallinac (Redi), a chicken mite, Dysdercus suturellus, a cotton stainer).

Jennings and King mention F. Knab's four factors necessary for an insect to be a potential transmitter of disease to human beings: 1. Habit of biting man regularly. 2. More or less close association with him. 3. A certain degree of longevity. 4. Abundance of the insects.

I mentioned to a lawyer friend the possibility of the fly being the winged host of a parasitic obnoxious to man and suggested "mites," "red bugs," or "jiggers" as carriers of disease. He promptly replied that he had been bitten many times by "red bugs" and did not have pellagra. So have the people of California been bitten many times by fleas, and they do not have the plague. Consequently we must add a fifth condition to Knab's four factors: The biting insect must be infected.

Flies, all species, mosquitoes and the simulidae all carry parasitic mites. Are they predaceous and obnoxious to man? This remains to be seen. So long as the good housewife gets pellagra twice as frequently as the man in the field we may suspect something about the house; but there is a drawback even to this, as among nulliparous women the sex incidence is even. Pellagra is the best gynecologist since Marion Sims's time.

We have one analogy of a predaceous parasitic mite being obnoxious to man. Schambert and Goldberg describe such a mite, Pediculoides venricosus of straw disease, and the entomologist Banks has identified and classified this mite. It is predaceous upon the larvae of the angoumois grain moth (Sitotrogo cerealella), the wheat straw worm (Isosoma grande, Riley), and the joint worm (Isosoma tritici, Fitch)—a small black fly the size of a gnat. This mite bites vigorously. Any one having camped at Gettysburg is probably familiar with its bite. The foregoing does not fix the etiology of pellagra upon the fly as a winged host, nor on a predaceous mite (Leptus americanus); but it does place the burden upon any doctor or entomologist attempting to prove or suggest the fly as the carrier host of a disease, to prove the flies free from predaceous parasites obnoxious to man.

Any fly theory of pellagra is open to two possible modifications by mites. First, the mite limits the fly population by destroying the fly larvae. If the fly is proved to be a carrier of pellagra and the mite is its natural enemy, the mite plays a role in the waxing and waning of this disease through the destruction of fly larvae. Second, the fly is a winged host of this mite which may be regarded with suspicion. We know of one fly, the wheat joint worm (Isosoma tritici, Fitch,) carrying a parasitic mite obnoxious to man, as described above. And, furthermore, Banks has described these larval mites on simulidae, flies, and mosquitoes. R. M. Grimm says on the relation of pellagra to the 296 families investigated:

In this connection there might be mentioned a fact which seems to me to be of considerable importance. This fact is that in many instances where the family had one or more cases of pellagra some one or perhaps several other members of the family would be found to present signs and symptoms very suggestive of pellagra, but to an extent not sufficient for a positive diagnosis. These signs and symptoms in many instances seemed to differ from those presented by the pellagrous member only in degree and not in kind. Among the symptoms in question may be mentioned mild gastrointestinal or nervous disturbances, the presence of a beefy or of an abnormally red tongue. The previous histories of some of these cases were also very suggestive of pellagra. Persons presenting signs and symptoms such as these were also seen in several of the pellagrous communities who were not members of families having definite case of pellagra. There were seen a great many of these borderline cases, the diagnosis of which was not always made with ease. For purposes of advice and treatment these cases would undoubtedly be considered as early cases of pellagra and in fact this diagnosis was the most probable one in the majority of instances, but for the purpose of my work.
they have not been considered as true cases of pellagra, on account of the element of uncertainty in the diagnosis. I have learned that some of these cases which were only suggestive of pellagra at the time of my visit have since developed the disease in pronounced form and succumbed to it, so without doubt it was the very early stages of the disease from which some, at least, of these persons were suffering at the time of my visit. The fact that many such cases exist is of considerable importance in considering the pellagra situation in a family or in a community, and, although it cannot be considered as evidence definitely positive, it may, with propriety, seem to me, be considered as data of an important collateral nature.

Grinnis has seen pellagra early and admits it, but thinks it only may "be considered as data of an important collateral nature." What opportunity is there in arriving at an etiological factor in a disease that is admitted to exist nine months before an absolute diagnosis can be made, that then runs a well defined course which the ordinary farmer in many parts can diagnosticate, and terminates in insanity, death or recovery as the case may be? What opportunity is there two or three years after the onset of the disease to discover an etiological factor? Some of those early cases, in which laparotomy is performed for gallbladder drainage and appendectomy, present the opportunity to study the sterile fluids of such drainage with profit.

Pellagra, in my experience, begins and for six to nine months remains as a mild catarrhal indigestion confined to the upper abdomen. I have had four opportunities to verify this conception; two I accepted, one I refused, and one patient was admitted to the hospital and died during my absence. The patient refused operation and the patient not seen by me both died in the same manner; both vomited themselves to death. The former was on rectal alimentation for six weeks. The two gallbladder appendectomies are both well and have passed one summer without relapse. In both cases there was evidence of pancreatic lymph nodes and some firmness of the head of the pancreas.

Appendicostomy, to my mind, is, like the entomologist, nine months behind the infection, or the neurologist two years later. Appendicostomy is done about twenty feet from the primary seat of the disease. While almost any operation apparently improves pellagrin by stimulation of the bloodmaking organs, and, to my mind, any necessary operation is actually demanded that will improve these patients' well being. For instance, note the preponderance of pellagrin among females suffering from birth traumaism which one reads in the statistics of every field investigator on this subject. Motherhood pays the penalty. Let me indicate how far one may safely go in this matter by quoting three operative cases. One of the patients only knew had had pellagra the previous year, and she had a completely lacerated perineum three inches up the rectum; the two unknown cases were both well marked cancer of the cervix and lower uterine segment. In the perineal case the patient was pellagrously emaciated and controlled the bowel by constipation. She made one eventful recovery and is in good flesh, without a pellagrous relapse for one summer. The two cancer patients, after a vaginal hysterectomy in each, went insane, one four days, the other seven days after operation. The earlier insanity lasted the longer and dry, brannlike scales, sharply demarked from the smooth skin of the forearm, told part of the story. The second patient broke out with a good rash, and admitted a previous one the year before.

Both of these patients are in a perfect state of health as to cancer, and did not suffer a pellagrous relapse last summer. Moreover, I shall never again stand idly by with a stomach tube in one hand and a rectal tube in the other while a pellagrin is in need of drainage. Gallbladder drainage is the operation of election, because it is as high in the alimentary tract as it is necessary to drain, and, being an operation of election, should be accompanied by an appendectomy. There is no telling how many microbes this little tube will hold.

I have observed patients recover from pellagra by such a variety of treatment that at first I thought it to be all a matter of chance, but later I began to look for some fundamental factor. Patients have recovered in the Shelby Hospital by surgical operations upon the gallbladder, appendix, and pelvic organs and muscles. Patients have recovered by the use of strong drugs, especially metallic drugs. Two patients have recovered spontaneously. The possibility of a patient in the lowest state making a spontaneous recovery should warn the physician never to give up. The first spontaneous recovery occurred in a woman who has now passed two summers without a relapse. I saw this patient six months before any pellagrous symptoms began. An old Potts's disease of the spine was beginning to warp her back. She came down with an acute attack of pellagra, and went from bad to worse until she lay on the bed in a state of suspended animation. She had a marked rash on the arms and neck. In this condition I photographed her. The picture appears like that of a cadaver. Within ten days the woman walked out of the hospital, and has been well ever since. Just prior to her three days of coma a leucocytosis of 14,000 was noted. Differential count was not made. In the second case, spontaneous recovery occurred twice in the same patient, in the practice of one of our Shelby physicians. Twice he gave this patient up to die, and twice his patient recovered by the aid of a "quack" water. For diet and appropriate treatment both of these patients would have made good additions to statistics. Unless the profession makes an earlier diagnosis and obtains more cures, a most excellent opportunity is offered to the quack. A number of pellagrin presented themselves to the hook worm dispensaries last year, the first time that they were seen by any doctor, and the inevitable followed. Pellagra was cured by thymol.

Again the necessity of finding a uniform factor in the recovery of pellagra presents itself. I regard pellagra as a medical disease which may at times be relieved by surgical interference. As I have mentioned before in this paper, gallbladder drainage with appendectomy is the operation of election, and may have a twofold effect on the disease. Early in the disease some patients have a slight catarrhal jaundice. As the gallbladder is a very suitable reservoir for many microbes, it is possible the pellagra germ may lurk here. At least drainage of the gallbladder relieves the pancreas and upper bowel, while the mere presence of a drain
sets up a leucocytosis over a number of days. Appendicostomy has been done with success in pellagra, but aside from the benefit of a continued leucocytosis the drainage is not high enough in the intestinal tract to be of service. In the normal man we have three diverticula. Two, the tonsils and appendix we may remove. The gall ducts we can drain.

Any surgical procedure on pellagrins has been attended with success by me. First, I have put the patient in a way to complete health, and, second, I have stimulated the hematopoietic organs to such an extent that my patients have escaped one year without a return of pellagra. Three cases relapsed immediately following operation and two others became insane—operated upon for cancer of uterus—and relapsed. All are in good health to-day. They owe their recovery from pellagra to a leucocytosis surgically incited. This fact I shall prove to your satisfaction by the action of colloids and strong drugs upon pellagra. E. H. Martin, of Hot Springs, in a recent article on the use of sodium acetylarsenilate, has added more evidence to this point. He claims that in the use of this drug you should get a reaction, which he claims is due to the destruction of parasites and the releasing of their antibodies. And, furthermore, you should administer it as long as you get a reaction, because you are killing microbes. I have given about four hundred intravenous injections of metals, metallic colloids electrically prepared, and organic colloids of metals. Chief of these are antimony, copper, selenium (Wassermann), silver, arsenic, and iron. Antimony, copper, arsenic, and iron have been used in pellagra; copper and selenium in inoperable cancer; arsenic in syphilis; and iron in tuberculosis, kidney enema, etc. The most electrically positive metals, such as copper, provoke the greatest disturbance—the so called reaction.

Clinically this reaction begins shortly after the administration of a colloid. In the electrically prepared metallic colloids after the manner of L. Loeb or G. Bredig in my hands, a chill began forty-five minutes subsequent to administration, accompanied by a rise of temperature to 102° to 104° F., and a corresponding acceleration of the pulse, headache, nausea, and sometimes emesis. Upon examination of the blood before, during, and after, this chill a pronounced leucocytosis is seen to begin, increase, and disappear, with the temperature curve. I have been able to produce at will a leucocytosis of from 15,000 to 20,000 within forty-five minutes of the administration of the drug. In nine hours the leucocytosis has disappeared. What has become of it? When a reaction is produced daily, a septic chart is limated, or if every other day, a tertian fever curve will occur. As this reaction curve is in the hands of the man that wields the needle, I have called it an aseptic chill. Twice weekly is as frequently as I have ever used it.

The leucocytes that are called up by the hypodermatic or intravenous administration of strong drugs are unique. When the first reaction is provoked the polymorphonuclear leucocytes are 98 per cent. of the entire differential count. This, as you know exceeds, Sondern's leucocyte resistance line which he indicates as a failing resistance. As the use of strong reactions is continued, the small mononuclear leucocyte enters the count in increasing proportion; with still more injections the large mononuclear leucocyte begins to occur more frequently; and if the use of the colloid is continued, large mast and bone marrow cells make their appearance. Finally a decrease in the red cells is noted and a few irregular red blood cells appear—poikilocytosis. Here I have terminated the use of electrically prepared colloids. To the cytologist the phenomena within the polymorphonuclear leucocyte is interesting. The chromatin has lost its usual resting shape and is unravelled like a skein of yarn and thrown into loops, ovals, and giant peripheral rings, generally open at one place. The cytoplasm is clear and very translucent.

In using the organic colloids of metals the above mentioned reaction may be absent or if present is never so excessive as that produced by the electrically prepared colloids. Do these increased leucocytes become phagocytes? I do not know. I am an ardent follower of Metchnikoff and Wright, but I have no means at hand to prove these cells active. Clinically, the patients improve in well being. A muddy copper colored skin soon begins to show a healthy flush; there is a gain in weight. I have reported a case of spontaneous recovery from pellagra with a leucocytosis of unknown origin; I have quoted E. H. Martin's statement, showing the necessity of a reaction to sodium acetylarsenilate as essential to a cure of pellagra! I have shown the effects of colloids and strong drugs upon the blood making apparatus, a generous leukocytosis created at the will of the doctor, and I have reported pellagra recovering from a variety of surgical procedures which were undoubtedly accompanied with a mild surgical leucocytosis.

Whether or not a more or less active leucocytosis should be provoked early in pellagra remains for experience to determine. I have shown the way.

All authors agree that pellagra is a disease of hypoleucocytosis, excepting the typhoid state, in which a low grade leucocytosis exists. The few cases I have seen in this condition were so overwhelmed by their infection that nothing seemed to relieve their helpless state. There is one more factor to support the good results obtained in pellagra when a leucocytosis is created early in the disease. This is a negative factor, but it obtains. Drugs depressing the blood making apparatus militate against recovery just as effectually as the drugs which stimulate the blood making apparatus act favorably. Alcohol and opium act unfavorably. I have recently read of the favorable action of opium on pellagrins, but I have personally seen several pellagrins progress from bad to worse and final dissolution on opiates.

An early diagnosis, diet, and treatment as outlined by Wood, Martin, Niles, and many other specialists on this disease, give the most favorable results. A late diagnosis, and then the internist gives the surgeon a chance.

Pellagra is a nonleucocytic disease. Pellagrous infection is symbiotic with nonleucocytic diseases, such as malaria, typhoid, tuberculosis, cancer, preg-

 referenced

hancy, and the puerperium: or it may follow such leucocytic diseases as exhaust the blood making or- gan, as pneumonia, septicaemia, etc. In my experi- ence when a leucocytic disease or reaction is grafted upon a pellagrous patient, whether from the effects of surgery or surgical diseases, or the beneficial ef- fects of a reaction to strong drugs, or a spontaneous leucocytosis, pellagrins make a slow but satisfac- tory recovery from their pellagra. To date none of my patients have relapsed. All have passed one summer and some have passed two summers.

A number of things are to be avoided by the pel- lagrin. Pellagra does not improve, but has a ten- dency to grow worse in alcoholics, morphine hab- itues, with excessive consumption of corn products, a low protein diet, and from the effects of direct sunlight. Any medical or surgical procedure which tends to restore the individual to the normal is beneficial to the pellagrin.

Pellagrous morbidity is greater than the birth rate in the Piedmont section. That the disease may be transmissible is suggested from the number of cases seen in the same house. All, however, may have been subjected to the original infection. Among the children certainly some have acquired pellagra after birth. As pregnancy has added to a fatal termination of pellagra I am not prepared to state the condition of the offspring. However, one would naturally suspect that an overwhelming in- fection would pass the syncytium. Is this heredity or environment? Incidentally, in the aborted fuses of the pellagrins lie many laboratory possi- bilities of antibodies and antigens. What we need is a specific blood test to enable us to make an early diagnosis in pellagra. This fact is clearly borne out by the report of the Illinois pellagra commission. They found a low protein diet among their insane, and it is a well known fact that a generous protein diet is favorably borne by pellagrins. On the other hand, I am surrounded by pellagrins, and the inhab- itants in all walks of life invariably eat two differ- ent proteids at each meal. The proteid is certainly not an etiological factor in pellagra.

Besides urging the avoidance of those articles of diet that apparently depress the well being of the pellagrins, it certainly should be the duty of the physician to advise the female pellagrin against pregnancy. This is a new role for the physician, but by any one watching the unimpeded progress of a pellagrous infection accompanied by pregnancy this advice will be well accepted. Of two cases in which pregnancy was terminated to save life, one patient at the third month recovered, while one at the sixth month rallied only to sink deeper into a typhoidal pellagra and death.

An early diagnosis, proper diet, and treatment place pellagra entirely in the domain of modern medicine. A specific test, such as the Bordet test, is within reason. To one looking over the thin scrawny offspring of the pellagrins, it is reasonable to presume that the aborted placenta and fetus con- tain sufficient antigen to set up a specific reaction in vitro. One in twelve pellagrins are surgical and can be treated by drainage. Lastly, an absolutely unfavourable prognosis should never be given to a patient, because the most unfavorable case may make a surprisingly rapid recovery, and chiefly be- cause the recovery from pellagra depends upon an happy frame of mind.

The New Pocket Clinical Sphygmomanometer.

By L. Napoleon Boston, A. M. M. D., Philadelphia.

Professor of Physical Diagnosis, Medico-Chirurgical College; Physician to General Hospital; Pathologist to Franklin Hospital.

The instrument here described presents certain decided advantages to the clinician, in spite of the large number of instruments now in use for the determination of blood pressure.

This pocket instrument has in common all the essential factors of the most modern instruments now in use, and in addition possesses unique features which, I believe, will bring it preeminently into favor. The pendulum has swung from the large and crude instrument of earlier days to the compact watchlike aneroid now universally employed.

The additional practical features of the new pocket clinical sphygmomanometer are:
The instrument when resting in its closed case is anchored to a false bottom which fits snugly in the case; the false bottom and instrument are removed together, and there is a neat receptacle at one end of the case which serves to hold the false bottom at a convenient angle, and this places the dial in the most suitable position. Again, when the instrument is ready for use, the entire case may be placed upon a stand or a bed, and, still more important, it may be shifted to a position where the patient is unable to observe the record.

b. The scale is extended to read to 350 m.m.

c. The dial is enlarged to a size which makes the reading easy at some distance from the instrument.

d. All graduations are at 5 m.m.

From actual experience with this instrument, it would seem that through it a happy medium has been reached. While all the above mentioned new features connected with the improved Faught instrument give it a decided advantage in clinical work, the one feature that stands out conspicuously to the clinician is, that the scale is graded to 350 m.m., which will doubtless make it possible, through the aid of this instrument, to obtain an accurate reading in each and every case. Again, the distance between the graduated marking on the dial makes it likewise easy to obtain abnormally low pressures.

This instrument is attractively finished in white and gold and is contained, complete with arm band and pressure pump, in a case of a size to fit any coat pocket. It is made by G. T. Pilling and Son Co., of Philadelphia.

1819 Chestnut Street.

THE MENTAL SYMPTOMS OF RENAL INSUFFICIENCY,

*With Report of a Case Showing Remarkable Subnormal Temperature.*

BY WILLIAM BURGESS CORNELL, M. D.,

Baltimore.

That disturbances of the renal function may give rise to abnormal mental symptoms has long been recognized. In the following brief review of the subject, it is proposed to limit the term renal insufficiency to that due to any form of acute or chronic nephritis, either primary or secondary. It seems reasonable to expect, as we have kidney lesions varying quantitatively from a very slight departure from normal to the most advanced state of renal degeneration, irrespective of the lesion qualitatively considered, that we would have pari passu, a great variety of nervous and mental symptoms of increasing severity. The symptoms, in the words of Herrick, are “in number legion, and in variety protean,” and run a gamut from simple headache to delirium and coma.

Although, nosologically speaking, the mental symptoms of renal diseases are usually denied an entity, the importance of their recognition and proper estimation can, nevertheless, be hardly underestimated. For, upon the correct diagnosis depends, to a great degree, the outcome of the case. Frequently the diagnosis of kidney disease is fraught with difficulty, particularly in the chronic interstitial variety, and in the latter occasionally the mental upset first directs the attention to the condition of the kidneys. Uremia has been defined as “an autointoxication which affects mainly the nervous system” (Wells). It is interesting to note that the patients are usually of neurotic type, with faulty heredity. In this connection also it is important to observe that a “distinction must be made between the psychogenetic factors that may determine the character of a psychosis, and the somatic conditions that determine its occurrence.” (Neff.)

Bearing this in mind, let us pass on to the enumeration of the symptoms themselves. Taking up first those of the suburemic state, it will be recognized that many of these are the nervous symptoms of the chronic neurasthenic. Headache is one of the most frequent and earliest, also vertigo. Another one of the earliest is a feeling of tension in the muscles. The patient has fits of the blues, and is easily discouraged and fatigued. Other symptoms are irritability, moroseness, insomnia, neuralgia, tinnitus, and a tendency to a slight degree of confusion. In the severer suburemic and uremic states we may meet with the following changes:

Consciousness: Confusion, drowsiness, obtundity, disorientation, delirium, semicoma, and coma. Since the writings of Addison, in 1839, and Lasegue, in 1852, all authors have called attention to the mental obtundity and dullness in nephritic cases; and Régis and others later recognized confusion as the commonest symptom of the whole group of nephritic psychoses. The others have been given in order of progression and severity.

Attention: An inability to fix, and a lack of power of concentration.

Intelligence and judgment: A general lowering and deterioration. Delusions of paranoid and persecutory type. (“Folie Brechtique.”)

Memory: An amnesia, more or less complete, with retrograde character, often developing into typical pseudoreminiscence.

Motor and psychomotor field: Sluggishness of thought processes, convulsive attacks, monoplegia, and hemiplegia.

Speech: Aphasia, which may be transient, and a speech defect best characterized as thick, hesitant, deliberate.

Hearing: Deafness, which may be transient, and hallucinations.

Vision: Diplopia, amaurosis, and hallucinations, usually of unpleasant and terrifying nature.

*Read at the Sixtieth Anniversary of the Founding of the Sheppard and Enoch Pratt Hospital, Baltimore.*
Affect: Excitement, sometimes of ecstatic type, or depression, which may be accompanied by anxious expression and agitation, or by apathy.

Regis divides the psychoses of Bright's disease into acute and chronic. Acute symptoms are usually preceded by more or less pronounced signs of uremia, which runs a rapid course. There may be delirium, hallucinations of terrifying content, motor disturbances, such as choreiform movements, grimacing, posturing; the latter sometimes re-embbing the cataonia of dementia praecox, and self accusatory ideas. It is interesting to note that often these patients are worse at night. Remissions, or semilucid intervals, are fairly frequent, and may last from a few hours to a number of days. In cases that do not succumb to the uremic condition acute symptoms are followed by intellectual obtundity, and sometimes certain of the ideas based upon fallacious sense perception remain as fixed delusions. Chronic symptoms are qualitatively similar to the acute, but spread out over a much longer time. The resemblance of this variety to chronic alcoholic hallucinosis and alcoholic pseudoparesis has been noted by numerous observers since the original report of Florant and Spigaglia in 1891.

The case which I particularly wish to report is one of the latter group. At first the diagnosis was in doubt, then alcoholic pseudoparesis was decided on, owing to the rather long and prominent history of alcohol. However, the subsequent course of events, and the death in uremic coma, determined that we were dealing from the beginning with a chronic uremic psychosis, although, unfortunately, no autopsy could be obtained.

The patient was admitted to the Sheppard and Enoch Pratt Hospital about the middle of 1909, and died six months later. The history given by the family put the onset at least five years preceding admission, when his face and hands were puffy and his family feared he had nephritis, although repeated examinations of the urine were reported negative. About this time he had a fainting attack and fell on the street. Then hallucinations developed and he was seen being followed and watched, and that some one was trying to rob him. He expressed suicidal intentions. He improved considerably after this attack, clearing up mentally to a certain degree, but never was quite himself again. There were in all, three periods of unconsciousness prior to admission, and all of these were followed by hallucinations and delusions of a paranoid and persecutory nature, which tended to disappear; a certain amount of irritability and deterioration persisted. After the last attack he showed confusion and memory defect. He wandered aimlessly about, particularly at night, and was then committed and brought to the hospital. The physical examination showed smallness and pallor of skin, puffiness of eyelids and hands, and edema of the ankles. There was a general cutaneous hyperesthesia, and the deep tendon reflexes were all exaggerateid; no evidence of arteriosclerosis. He swayed somewhat in Romberg's position. Spinal fluid showed 1250 cells, 99 percent of protein, but no increase of cells. Wassermann reaction was not performed. Mentally, he gave his age correctly as fifty-three years, and was oriented for place, not in time. Insight was partial; knew only that something had been wrong for a long time. Apperception of time and memory defective, particularly for recent events. He entertained delusions of a persecutory type; hallucinations were present, the auditory type predominating. Speech was thick and defective; he stumped habitually the correct phrases. He seemed very uncomfortable, and made no mention of the physical nature, was low, or irritating to nurses; at other times childish in manner. Seemed physically weak. Retained ideas that he was poisoned before coming to hospital. Urine examination showed considerable variation, at times no albumin, or casts being reported; the twenty-four hour amount was usually much diminished, but the specific gravity was usually low. After several months his general physical condition seemed to improve; mentally there was considerable fluctuation. For some days he would appear brighter, and than he would lapse into a sluggish, confused state, in which the delusional and hallucinatory ideas would become more active; or he would make more complaints of a hypochondriacal nature. The condition of the bowels, usually constipated, but occasionally loose, seemed to worry the patient greatly. Finally, after a short prodromal period, not unlike others he had had, of weakness and malaise, he lapsed into a comatose state. It was noted that the body temperature was not very high, and inserting the finger in the mouth gave the sensation as if ice had been held therein. The mercury of an ordinary clinical thermometer failed to move above the lowest mark, and one obtained from the laboratory registered the remarkably low temperature of 83.3° F. rectal, and 83.5° F. by mouth. This was very little influenced by various applications of heat; and although the mental state cleared somewhat, the patient sank later into a deep coma, followed by death three days after the inception of the severe uremic symptoms.

The mental symptoms in this case undoubtedly followed changes in the renal functioning. The possible similarity of alcoholic and uremic psychoses, already referred to, may have a common factor in an abnormal kidney; indeed, this has led some writers to believe that the majority of the toxic deliria classed as lead, puerperal, typhoid, scarlatinal, etc., are determined by concomitant renal disease. In this connection it is interesting to consider the relation the latter may have to other psychoses, as suggested by Doctor Neff's review of 1,180 autopsies in the Morristown State Hospital. Excluding all cases over sixty years of age, also all paretics, epileptics, and organic dementes, there remained 258 cases, clinically manic depressive and paranoia, ninety per cent, of which showed varying grades of kidney disease.

Of the many possible variations in the urinary output the best known and most constant ones paralleling uremic mental symptoms are changes in the specific gravity and the twenty-four hour amount, but the new renal functional test, according to Rowntree and Geragthy, using phenolsulphonephthalein, undoubtedly will prove of great value in better and more accurately detecting renal insufficiency, and likewise establishing the latter as the etiological factor in the psychosis.

It is hardly necessary to add a word as to the prognosis. In the uremic psychoses the outlook is graver than the other toxic psychoses. Of course, the state of the kidneys swings the balance one way or the other. Recovery in the milder cases may occur, but relapses must be expected, and in the severe acute and chronic cases the situation is well nigh hopeless.

In conclusion, let us not forget the important bearing of the renal function upon the psyche, not only in the so called nephritic psychoses, but in other and less understood forms of abnormal mentality. The realization that very little is known of the common underlying etiological factors should form a great incentive for clinicochondrom work in this direction that promises brilliant results in psychological medicine.

606 Union Trust Building,
Surgical Aphasia.*

By William L. Chapman, M. D.,
Brooklyn,
Attending Surgeon to the Swedish Hospital;
H. A. Morris, M. D.,
Brooklyn,
Assistant Surgeon to the Swedish Hospital;
and G. W. Simrell, M. D.,
Brooklyn,
Assistant Surgeon to the Swedish Hospital.

The term "surgical aphasia" is applicable to a certain class of cases wherein the speech centres have been injured or inhibited by trauma to the bones of the skull or by growths encroaching upon them. They must be cases which hold out some hope of relief from surgical procedure. No other form of aphasia can be considered under this title. It is essentially a condition produced by pressure, or the effects of pressure, upon the nerve cells of the speech centre. The field, therefore, is exceedingly limited.

Etiology.

The etiology may be considered under two headings, viz.: neoplasms and trauma. Tumors or cystic growths occur in the speech centre, as well as in any other region of the brain, but as the writers have had no personal experience with them, they will receive but passing mention as possible etiological factors. The only conditions met with which might be considered in this class are exostoses and osteophytes, and these are the results of trauma.

The exposed position of the head, with the slight protection which the scalp affords, renders it freely accessible to injury through falls or blows, but the most frequent cause observed has been from the use of obstetric forceps during delivery. About eighty per cent. of all cases seen by the writers could be traced to this cause. This is not surprising when one considers the condition of the bony tablets at birth and the amount of pressure frequently exerted upon them. As a rule, the induration made by the forceps blade soon disappears, owing to the elasticity of the then cartilaginous bones, but in some cases the inner tablet is split, a callus is formed upon its inner surface through the escape of osteoblastic cells, and thus the dent remains. In any injury to the head the inner tablet is more liable to fracture than the outer, for while any force applied to the skull causes only compression of the outer tablet, it puts the inner tablet upon the stretch. Epidural and subdural hemorrhages may result from the same pressure, either by laceration of the bloodvessels of the meninges or from exposed diploe. As a rule, the blood from these hemorrhages is absorbed, and therefore they produce no pathological changes, but in some cases fibrinous collections remain and form adhesions, producing pressure by their own bulk, or by promoting the development of bone cells which have escaped through the laceration of the inner tablet, at that time practically a membranous endosteum. The cranial hemorrhages which occur at partition have been studied exhaustively by Cushing, of Baltimore, and Rawling, of London.

Pathology.

The pressure effects upon the brain centres may be divided into those of the first and second degrees. Those of the first degree produce only inhibitory or functional disturbances, without structural changes within the brain substance, while those of the second degree produce destruction of the nerve cells, either by direct violence or by atrophy from long continued pressure. Hemorrhages produce changes in the same manner, that is, those from the meninges or diploe produce changes of the first degree, while those within the brain substance produce changes of the second degree. The question has been raised in the cases operated upon whether the patients were not suffering from mere psychoses which the shock of the operation removed, and which would have eventually disappeared without operation. The only answer that can be made to this question is that psychoses do not produce bony depressions or meningial adhesions, and that it was not until after the removal of such depressions and adhesions that speech was restored.

Indications for Operation.

Indications for operation are frequently difficult to determine, and these difficulties are often complicated by the untruthfulness of parents or guardians. It is an astounding fact that in these unfortunate cases parents will sometimes deliberately lie in order to secure an operation upon their child's head, in the vague hope that thereby some miracle may be performed. The frantie desire of parents and friends to secure relief for defective children often leads them, in detailing histories, to exaggerate the importance of any slight fall or injury. In this manner parents are very apt to persuade themselves, and try to convince the surgeon, that some very insignificant injury has resulted in the whole trouble. When confronted with the surgeon's opinion, based upon cross examination and final analysis, that the result of an injury has probably had nothing to do with the mischief, they will often exclaim, "Please operate anyway, and take a chance; I would rather see my child dead than the way it is." The heartrending scenes witnessed in many of our neurological clinics are enough to cause many operators to shrink from the field of cranial surgery.

One thing is certain, it is useless to attempt any operation unless the organs of special sense and all other mental faculties are normal. In order to determine this it is frequently necessary to have the assistance of the neurologist, otologist, and laryngologist. All cases should receive most rigid examination. All other forms of aphasia should be excluded by the neurologist. The question of congenital deafness should be settled by the otologist. The laryngologist should examine for adenoids, enlarged tonsils, and congenital defects of the nasopharynx, palate, and vocal chords. X-ray examinations are of uncertain value. All the cases operated upon thus far in which the operation has proved beneficial have had a positive history of trauma, and in most cases a depression could be de-
ected by digital examination. In making digital examinations of the skull care must be taken not to mistake the normal ridges and depressions of the skull for abnormalities, as the normal ridges vary in different subjects.

PROGNOSIS.

No prognosis should be made previous to operation, as the extent and effects of a given injury cannot be determined until after the skull has been opened. Certain points in the case may, however, be considered. The age of the patient and the duration of the existing condition are important factors. The older the patient and the longer the lesion has existed, the less favorable the prognosis. Little should be promised to the patient or to his relatives and friends, for the disappointment which follows failure here is bitter with the bitterness of the hemlock cup.

SUGICAL ANATOMY.

A few words regarding the surgical anatomy are necessary. All textbooks on anatomy practically agree upon the topographical location of Broca's area, namely, on the left side (in all righthanded persons), one and one half inches posterior to the external angular process of the frontal bone and one and one half inches above the zygomatic arch. In reviewing the subject in Gray, Quain, Morris, Piersol, Deaver, and Campbell, one finds in their measurements differences of but a quarter of an inch, and as the ordinary trephine is one half inch in diameter, it covers these differences. These measurements, however, are made upon the normal adult skull, and are of little practical value here, as most of these cases are found in children of from four to ten years of age. But the method described by D. J. Cunningham, of Dublin, is applicable to all ages, and is the one followed by the writers. Cunningham locates the point where the greater wing of the sphenoid meets the frontal, parietal and temporal bones. This point is known in the infant as the anterior lateral fontanelle, and in the adult skull as the pteron. It is true that this point changes its position with the growth and development of the head, but during all its changes it follows and lies directly over "Broca's area." When the periosteum of the temporal fossa is elevated, the sutures entering into its formation are easily recognized, and the trephine may be applied directly over them.

SUGICAL TECHNIC.

The patient is admitted to the hospital the day before operation. Upon admission the entire head is shaved, regardless of age or sex. This is done with a thick lather of green soap and a safety razor. Special mention is made of the safety razor because of the natural resistance on the part of the child. After the head is shaved, it is rinsed with sterile saline solution and several times with a solution of bichloride of mercury. 1 to 1,000. It is then wrapped in several layers of sterile gauze soaked in bichloride, and a snug skull cap bandage is applied, the bandage being reinforced with strips of adhesive plaster. The child receives no medication whatever. If its bowels do not move, an enema is given in the morning. A light supper, usually bread and milk, is given at six p. m., and nothing more until after operation.

At the time of operation the patient is placed upon the operating table, lying upon his right side. The head is brought well up to the end of the table and placed upon a moderately low pillow. The anesthetic used is either pure sulphuric ether or A. C. E. mixture, according to the age of the patient. The head dressings are now removed, and the scalp again gone over with sterile soapsuds and the saline and bichloride solutions. All parts, except the immediate field of operation, are carefully protected by sterilized sheets and towels. A semicircular incision is made, starting at a point about three-fourths of an inch to one inch posterior to the outer canthus of the eye and running upward, backward, and downward, parallel to, and about one third inch below, the inferior temporal ridge. The incision is about two inches in length, but varies according to the case, and should be kept as far as possible within the area of hair growth, so that no scar will remain upon the forehead. The scalp is pressed through the soft parts of the scalp down to the bone, and made to feel the bone throughout its entire course. The flap thus formed is seized with a tenaculum forceps and pulled downward, while a few incisions free it from the bone. After all bleeding points in the scalp have been arrested the periosteum is incised along the line of the scalp incision, and, with a periosteal elevator, is raised and reflected downward over the scalp flap. The parts are now ready for the application of the trephine, the manner of which depends upon the conditions presented. If the depression is slight, the trephine may be placed directly over it, but if it is deep, or if there is reason to suspect much bony thickening beneath it, it is better to trephine above on the margin, and then attack the ridges with the rongeur and bone forceps. After the button of bone is removed the depressions and adhesions can be located by a blunt probe or grooved director. All depressions and adhesions should be followed and removed to their entire extent. Should the dura be found adherent to the underlying structures it should be incised and freed. This is done by pushing the finger through the incision, and, while the edges of the dura are held with thumb forceps, depressing the brain beneath, thus tearing it free from the adherent dura.

The wound is now closed in the following manner: no bone is replaced; a few strands of plain catgut are laid across the opening for drainage, the periosteum is drawn over these and sutured with No. 1 plain gut, interrupted sutures; the scalp flap is sewed down with No. 2 plain catgut, the sutures passing down through the temporal muscle, and so located as to include the clamped bloodvessels. This completes the operation, except for the ordinary head dressings.

The most recent work on cranial surgery, by Rawling, lays great stress upon the difficulties of controlling hemorrhage during cranial operations. The writers have not met with any of these difficulties, and the cranial tourniquet has not been used in a single case. The vessels of the scalp are easily controlled by pressure clamps; the clamp cannot be applied directly to the bleeding points, but must include the entire thickness of the scalp. If the flap is quickly turned back, this is easily accomplished. The bleeding from the dipoles is usu-
CHRONIC APPENDICITIS IN ITS RELATION TO HYPERACIDITY OF THE GASTRIC JUICE.

A Clinical Study.

By H. ILOWAY, M.D.

New York.

(Concluded from page 1687.)

II. APPENDICITIS SETTING IN IN THE COURSE OF A HYPERACIDICY OF THE GASTRIC JUICE FROM OTHER CAUSES.

Case I. December 6, 1900. J. J., male, referred by Doctor S. Age, twenty-three years, single, clerk; height, five feet, four inches, weight at most 114 pounds. Average weight 111-113 pounds. Smokes two or three cigars and one cigarette a day; drinks only rarely; a glass of beer or a little brandy once in two or three months. He has been troubled with his stomach for over a year, having attacks of indigestion at irregular intervals. He suffers from epigastralgia. He is very nervous; has suffered after a hearty meal, as after his dinner in the evening, when he feels a pressure even in his back, about the eleventh vertebra and a little to the right of the vertebral column. About six months ago he lifted a piano, and since then he has had a pain in the right half of the abdomen. It was at no time an acute pain, only a feeling of dulness, of heaviness, and now he complains of the whole right half of his body, a feeling of stiffness in the muscles of the leg. It does not disturb his sleep, but when he wakes up he has the same heavy feeling. His appetite is good. (Breakfast, shredded wheat biscuit, glass of milk or cup of coffee: lunch, some meat, glass of milk, bread and butter; dinner, in the evening, a regular dinner.) He drinks very little water (about two glasses a day). The bowels, he says, would move spontaneously every day, but because of the state of his stomach and the sensation in his abdomen he takes a purgative (or laxative) every other night. The heaviest pressure in his abdomen is, however, not relieved by this; it continues the same whether he is purged or not. Occasionally he feels "gases moving about in him"; this happens most frequently after meals. Tongue, clean; headache, rarely; sleeps well.

Examination: nothing abnormal on inspection or palpation. Slight sensitiveness in the median line; soreness along lower part of right costal arch border extending into right hypochondrium; also over the region of the gallbladder, but more marked in the right epigastrium at the site of the pylorus. (Point A.) No splashing; water six ounces, no splashing, no sound. Liver and spleen in normal position; abdomen, nothing abnormal on inspection or palpation; on the linea spina umbilicalis dextra, at a point 1½ cm. from the umbilicus to the right, slight soreness on hammer percussion, but more at a point further down, five cm. from umbilicus and two cm. to the right from the median line. On flexion and extension soreness at point A; but in lower quadrant of abdomen or over McBurney's point.

December 13th. Current temperature 101.2°; pulse 90; breath sounds normal. He was reexamined. He had undergone several examinations for the presence of worms; he had subsisted on a diet of bread and water, free tube for three days, and had been in bed. Reaction, blue litmus +; congo +; phoroglucin vanillin +. Free hydrochloric acid, thirty-nine, total acidity fifty-nine (on second trial for total acidity alone, sixty). Reexamined Upon the above mentioned findings; water, vegetables, etc. Locally over appendicular region, application of tincture of iodine, and ice bag at night. If not completely relieved in a reasonable time, operative interference to be considered.

Case II. November 22, 1900. M. S., salesmen, aged thirty-five years, married; children; height five feet, seven inches; average weight 138 pounds, here, without coat or waistcoat 120 pounds. He smokes one or two cigars and several cigarettes a day; drinks a little whiskey or brandy before dinner and before supper. Complains of severe pains in the stomach, cramplike, that come on at intervals; has had stomach trouble for the last six years. The last severe attack, previous to the present one, occurred about six months ago; the present attack began about a week ago. Formerly, despite the attacks, he always had a fine appetite and could eat well, only that three hours after the meal he would have severe cramps. Took sodium bicarbonate and was relieved. Lately, however, his appetite has failed and he has subsisted on bread and milk diluted with water. Last Sunday, feeling somewhat better, he ate two platefuls of chicken soup and about two hours afterward was seized with the cramps. Bowels, although usually regular, have lately become rather irregular. Sometimes he has diarrea, sometimes constipation, two or three times a day, and then again he will have two or three loose stools a day. Tongue: the anterior half clean, the posterior half covered with a yellowish white coating. Sleep good, when not broken by the cramps. Examination: Epigastrium, nothing abnormal on inspection or palpation; no sensitiveness (to hammer percussion) anywhere. No splashing; water, eight ounces, splashing in the upper segment of the epigastrium. Liver and spleen, in normal position, nothing abnormal. He is rather nervous; very fidgety.

November 23d. Test breakfast (Ewald and Boas): one hour; tube; obtained sixty c. c. stomach contents, bread and fluid, well mixed, emulsioned. Reaction, blue litmus +; congo +; phoroglucin vanillin +, acid, sixty-seven, total acidity seventy-seven. Diagnosis: hyperacidity; gastralgia. Treatment: Diet, for the present: Eggs, milk, crackers. To stop smoking and abstain from all alcoholic liquors.

December 2d. His bowels have moved seven times daily. The first stool was very hard; much so that a few drops of blood came with it. Says he gets pain in his stomach when it is empty. I ordered the hyperacidity diet usually directed by me+, and prescribed for him eight grains of bismuth subnitrate three times a day. In case of severe pain in the night to take half a grain of codeine, and to repeat the same, if necessary, in forty minutes.

He continued under observation (coming in every week or two) until April 18, 1911, and then ceased his visits. July 27th. Came in again to-day. He had been feeling well all this time and does not feel very badly now; he can eat nearly a whole chicken and sleeps ten hours every night. Last week (he had lived with his parents for many years and to whom he was greatly attached) died rather suddenly and he was very much affected thereby. He became nervous; had palpitations. He at once began taking the pills prescribed for him at that time (I had prescribed for him on a previous occasion and he was soon better). Then a pain in his stomach, sometimes cramps, set in, and this is his principle trouble now. Examination: Epigastrium, sensitiveness to percussion with a finger in the upper triangle. Abdomen, quite marked sensitiveness in the linea spina umbilicalis dextra at a point five cm. from the umbilicus, to the right.

Treatment: Apply an ice bag to the appendicular region. For the stomach, a powder of bismuth subtricate, calcined magnesia, and sodium bicarbonate. For the cramps in the intestines,precipitated magnesia, or opium with a wine glass of milk. Diet, only milk (warm) and soft boiled eggs. July 31st. Patient is better. No sensitiveness at all in the epigastrium; in the abdomen still slight sensitiveness over the point of tenderness. August 10th. Reported that on his way home. July 31st, he was suddenly seized with a pain so severe that he could hardly move. When he got home he at once applied the ice bag over the appendicular region, and was relieved in a short time. He still gets cramps in the intestines; and sometimes he gets cold as he gets out of bed, or he will have a cramp. August 6th. Feeling very well. No pain or sensitiveness on percussion in the epigastrium or the right half of the abdomen. Continue the ice bag from eight to ten p.m. (is obliged to work throughout the day) for the next four nights; then every other night for a week; then twice a week for a week. Continue the diet first directed (for the hyperacidity).

November 12th. Came in to-day because of a lumbar Abdomen normal; not the least trace of the attack of appendicitis.

February 3, 1913. Says he feels well, but at times has much flatulence; feels filled up with gas. Examination done, March 16th. The appendix was removed. The whole of the spina umbilicalis dextra. He says that after a hearty meal he can hammer his stomach and bowels without feeling the least sensitiveness anywhere. Once in a while he becomes depressed; gets the blues. Continue the hyperacidity. Apply an ice bag on the right hypochondrium at night for two hours.

Case III. September 19, 1911. Mrs. E. K., thirty, married; one child. Height five feet, five inches; weight last year, 175 pounds, now, here, 132 1/2 pounds: no alcohol or tobacco. Since the age of three she has had frequent hiccough. She regurgitated her food; it came up very sour. Milk came up curdled. She had pain in the epigastrium and right hypochondrium all the time and it became more when she belched; especially after frequently had hiccough. She came under the treatment of an eminent specialist for diseases of the digestive tract, was taken to a hospital, and kept there for five weeks, and was finally put to bed. A duodenal tube was introduced and kept in place for two weeks; through this she was fed during that period with milk and eggs. Under this treatment, she said, she grew worse, lost much flesh, became very nervous, and suffered greatly from soreness of the esophagus. When she left the hospital she went to see a Campagna, who sent her home with the advice to stop all milk and eggs, and stay in bed. She was in bed for six weeks, and there also she continued to grow worse. Now her symptoms are about the same. She complains of constant pain in the epigastrium and the right hypochondrium, but no particular point of tenderness; frequent regurgitations, sour regurgitations, and occasionally hiccough. Her appetite might be called fair. (Breakfast, two soft boiled eggs, a cup of milk, and one or two slices of stale white bread; dinner, soup (of chicken), boiled spring chicken, or soft boiled eggs, and tea without milk; supper, eggs, milk and bread). She drinks no cold water, as this causes discomfort. Bowels regular; no headaches; sleep, not very good; she wakes up after two or three hours; cannot fall asleep again; tongue has a heavy white coat.

Examination. Epigastrium, nothing abnormal on inspection or palpation; sensitiveness to percussion in median line from xiphoid cartilage to umbilicus, also in the umbilicus. Liver palpable. She said she had never had any about the bend of the right half of the costal arch. No splashing; water eight ounces, no splashing, no sound. Liver, normal in size, no sensitiveness or anything abnormal about it; spleen, normal; right kidney mobile (C.C.)(abnormal); left kidney fixed. Nothing abnormal on inspection or palpation; percussion with hammer causes pain on the linea spina umbilicalis dextra, especially about the umbilicus and for two cm. from it. Right hypochondrium, but no tenderness. About half of the abdomen, about the head of the rectum and across the pubis; no tenderness. September 21st. Test breakfast: one hour; tube; obtained fifteen c. c. stomach contents, bread and fluid, all well worked up together and presenting the appearance of an emulsion. Reaction, blue litmus +; Congo +; phoroglucin vanillin —. Free hydrochloric acid, forty-five, total acidity seventy-six. Pepsin nearly normal, but not in correspondence with the marked degree of acidity here present; rennet, normal. She brought with her a specimen (four ounces) of urine from a twenty four hour collection; appearance, transparent. Diagnosis, chronic nephritis. Diet, only milk (warm) and soft boiled eggs. July 31st. Patient is better. No sensitiveness at all in the epigastrium; in the abdomen still slight sensitiveness over the point of tenderness. August 10th. Reported that on his way home. July 31st, he was suddenly seized with a pain so severe that he could hardly move. When he got home he at once applied the ice bag over the appendicular region, and was relieved in a short time. He still gets cramps in the intestines; and sometimes he gets cold as he gets out of bed, or he will have a cramp. August 6th. Feeling very well. No pain or sensitiveness on percussion in the epigastrium or the right half of the abdomen. Continue the ice bag from eight to ten p.m. (is obliged to work throughout the day) for the next four nights; then every other night for a week; then twice a week for a week. Continue the diet first directed (for the hyperacidity).

October 24th. Weight increased to 137 1/4 pounds. She says she has not been free from the pain in her stomach, although at times it has been less severe. At such times the food does not regurgitate, but when the pain is more severe, she has a scalding sensation about the right half of the abdomen. On percussing the linea spina umbilicalis dextra she complained that it gave pain at a point 4 1/2 cm. from the umbilicus. Still belches and has hiccough (occasionally only) and the tongue is very scanty and at the same time very thick. She also complained of diarrhea. The tongue is also very sensitive. She has a chronic pharyngitis. Directions. Apply an ice bag to the appendicular region. Eight grains of bismuth subtricate fifteen minutes after each meal. A specimen of urine, containing 20 grains of bicarbonate of bismuth, was prescribed. For the next seven days, a brick dust deposit. October 30th. Says she feels bad on waking in the morning and cannot eat any breakfast. Her stomach feels full. The appendicular region is now very sensitive. On flexion and extension of the right leg the sensitiveness is only increased on the right. General extension. She says she feels soreness in this region when walking, but most of her suffering is in the stomach. Continue the ice bag. November 6th. She complains of the pressure in her stomach, mainly in the lower portion of the right half of the epigastrium and anterior portion of right hypochondrium. On examination, she cannot really locate the point of pain exactly, but the sensitiveness to pressure of the fingers is at and about the umbilicus. She came fasting, as she had been directed. Test breakfast; one hour; tube: forty-five c. c. stomach contents, bread and fluid. Bread well worked up. Reaction, blue litmus +; Congo +; phoroglucin vanillin +. Free hydrochloric acid sixty, total acidity seventy-six. Stomach full in glata and ecotopy. There were no other symptoms, except otherwise abnormal in the extracted stomach contents. To have her feces examined for occult blood. "Meanwhile to subsist on milk and Vichy (celestins). November 15th. X-ray Test found no change. Reexamination here. The pain on palpation is not so much in the stomach as in the appendix. As she points to it, the pain extends from the crease to the umbilicus and is mostly felt in the right half of the abdomen. It is a constant dull pain, with modifications up and down. On flexion and pressure of flexed thigh and extension, the signs of inflammation of the appendix are positive. Per vaginam, nothing special to be felt, but also there pressure made to the right causes pain. The ice bag did not help her greatly. Advised her to have the appendix removed, and sent her to a well known surgeon.

January 8, 1912. She came in to-day on her way home from the hospital, from which she had just been discharged, after having had an abdominal operation. A diagnosis of gallstones was made. She was operated on for gallstones, but none being found, and there being otherwise nothing abnormal about the liver, an appendectomy was made. I was informed that the appendix presented a condition of acute inflammation, and extended into the cecum. Numerous adhesions were said to have been found about these parts. Patient complains that she still has a very sour stomach and occasionally some pain. To-day milk, soft boiled eggs, white meat of chicken, still white bread. Vichy, Chamomile. She is not relieved, to take the bismuth, magnesia, and belladonna powders.

February ad. She says she is worse now than before the operation. Formerly she could eat, but since the operation cannot eat at all. When the pressure sets in, the configuration of her abdomen is changed. She is very
much depressed and cries freely and readily when speaking of her ailments. A specimen of urine she brought with her showed an abnormal presence of uric acid gravel. She came fasting, and wanted her stomach contents tested. They gave free hydrochloric acid forty-six, total acidity seventy-one. To have her stomach washed out every night.

February 25th. Patient did not have her stomach washed out until yesterday. It was done too early, and she lost her supper in consequence. Her physician called me up on the telephone with regard to this, and I repeated the advice to wash out her stomach about 11 p. m., and to mix prepared chalk with the water.

April 22d. I was informed to-day by her physician that he had lavaged her stomach five or six times without any apparent benefit. She then became pregnant and he stopped the treatment. She is feeling much better since then. About three weeks ago, during a gang fight in her neighborhood, a bullet entered her head and struck just above her head. She was shocked and some hours later began to have uterine pains and slight flow. Her physician was called, ordered the necessary treatment, and she recovered quickly. There is no doubt in my mind that the pregnancy has had a most beneficial effect upon her digestive and nervous systems.

In this section also more cases could have been cited, but the number reported are sufficient for the purpose. In view of what has already been said, it is but natural that the question should present itself, Is there, in these cases, any relation between the hyperacidity and the appendicitis, i. e., has the hyperacidity furthered the development of appendicitis or is it merely an accident that the latter has thus supervened?

If the former view be taken, it can be supported on these grounds: In many cases of hyperacidity a subacute inflammation has developed, or develops, in the gastric mucus membrane, and the irritation therefrom could be communicated to the appendicular mucus membrane in the same way as the irritation from the appendicular mucus membrane is communicated to that of the stomach, as already described. Or, it may be that some of the highly acid contents of the stomach, passing down through the intestine, get into the appendix and cannot get out again, as described in my book on Constipation, and there set up an irritation with spasmodic reactions in the same way as they produce, at times, cramplike attacks in the stomach itself (spasms of the pylorus).

III. APPENDICITIS AND GASTRIC HYPERACIDITY COINCIDENT (at least in so far as I was able to determine).

Case I. April 27, 1910. L. E., a Turk, twenty-one, single, clerk. Height five feet, eight inches; weight 140 pounds. Smokes cigarettes, but has not smoked any for the last five weeks; no alcoholic liquors. Enjoyed good health up to a year ago, when he began to have headaches—about once in two weeks. Always a good eater.

About seven weeks ago he was seized one evening after supper with a severe headache; things became black before his eyes. He took a dose of salts, went to bed, and the next morning took a bottle of magnesium citrate. He remained in bed for three days; then got up and went to a dispensary. He still complains of dizziness; has chills and somewhat feverish all day. He has lost five pounds. His bowels are open (he is taking medicine from the dispensary, which seems to contain some laxative drug). Has pain in the epigastrum. Sleep, good.

Examination. Epigastritis, nothing abnormal in inspection of stomach. The stomach is slightly sensitive, especially in the median line, from the xiphoid process to the umbilicus, and in the right half of the epigastrum. No splashing; water, eight ounces. Liver and spleen normal. Bowel sounds normal. Inspection: the right half very sensitive to hammer percussion and to the pressure of the hand. On flexion and extension, nothing very marked: an uncomfortable feeling in the appendix and lower half of the abdomen, more by comparison with the left leg. On percussion the abdomen is percussed he feels the hyperacidity of the epigastrum. Facies that of a patient in the prodromic or early stage of typhoid fever. No elevation of temperature. Diagnosis, reserved. Question: Appendicitis or typhoid? Treatment. Bed rest, bread and water, and soft boiled eggs only. To drink freely of cool water. When bowels are costive, to take an enema. Medication, a pancreosin tablet with meals. May 1st. Pain in right half of abdomen, most certainly relieved. Only felt on deep pressure, and even then much less than before. Tongue covered with a heavy yellowish white coat. Still some headache, which comes on after eating. Tincture of nux vomica, two drops every two hours, and strontium bromide, twelve grains at 10 a. m. and at bedtime. May 5th. Still pain and soreness over linea spina umbilicalis dextra, in the upper third; also in epigastrum; heaviness after eating; headache. Feels best when lying down. No elevation of temperature. To apply an ice bag over the appendix. For the epigastric pain a powder of bismuth, magnesia, and belladonna prescribed.

May 8th. In statu quo. Over the appendicular region, and downward, soreness on deep pressure; in the epigastrum a marked tenderness. May 10th. It has been going on in this way: some days the appendicular region seemed entirely free from pain and the epigastrum was very sore; at other times the soreness was most marked over the right half of the abdomen. Test breakfast—two hours; tube: sixty c. parts of stomach contents, bread and fluid; bread well worked up. Reaction, blue limus +; congo +; phloroglucin vanillin +. Free hydrochloric acid forty-eight, total acidity sixty-six. On inquiry as to why pain came on first, he said he did not know; he had not eaten the food before. May 16th. Last night he had an attack of very severe pain in the abdomen, as bad as at the beginning. All the pain is located about the umbilicus; right half of abdomen is very sore. There is some tenderness in the inguinal region, near the median line; has some pain in left half of abdomen: epigastritis very sore. Advised him to consult a surgeon with a view to an appendectomy.

July 16th. Owing to various delays, he was not operated on until the 6th of this month. He was discharged from the hospital to-day, and on his way home came in. Feels well; no soreness over epigastrum, though he is still somewhat sore in the lower half of the abdomen. He is right 125 pounds. To keep on a milk, eggs, and vegetable diet till the next week (though he has already had soup and meat in the hospital). July 19th. Yesterday he again had pain in the epigastrium; bowels were loose (due likely to some pears he ate). Test breakfast—two hours: tube: sixty c. parts of stomach contents, bread and fluid; bread well worked up. Reaction, blue limus +; congo +; phloroglucin vanillin +. Free hydrochloric acid, sixty-two, total acidity seventy-three. Gave him the necessary directions.

September 11th. Patient is feeling much better. Still some soreness in the epigastrum, though less than before the operation. Examination. Some sensitiveness in the median line, about crease; also in the right half of the abdomen and somewhat more at the middle of the line spina umbilicalis. He said he felt pain in the epigastrum. Pulse 72, rather weak. Weight 138 pounds. Continue diet as before. Compound syrup of hypophosphites, a teaspoonful three times a day.

December 4th. The patient has varied as to his condition, now complaining of pain, now frec: from it. Bowels costive or even constipated, and then again rather loose. Age 20. Complaining of loss of weight in his stomach, and was ordered some codeine tablets; half a grain to be taken at bedtime. December 6th. Still some pain in epigastritis and soreness on pressure. Bowels as before, sometimes loose, sometimes constipated. Weight 140 pounds. In view of this continued and steady gain in

91 Constipation in Adults and Children, with Special Reference to Habitual Constipation and Its Most Successful Treatment by Mechanical Methods, by H. Illoway, p. 137.

92 Pathomorphologic Sign etc., Archives of Diagnosis, June, 1908
low degree of the total acidity, I was certain that I had here a case of hyperacidity. I ascribed this low degree to the diet of milk and eggs in the three preceding days. In addition thereto, there is present a chronic appendicitis. 

TREATMENT. To lie down in bed and apply an ice bag over the appendicular region. Adhere to the appropriate dietary directions. November 19th. Had again severe pain over the appendix. She put on an ice bag and was relieved. She is very costive. To take an enema. I advised her to have her appendix removed, but she will not consent to this, because she is afraid of the anesthetic.

November 22d. To-day she had an attack of nausea and vomiting consequent upon an enema taken shortly after a rather large dinner of roast beef, vegetables, and dessert. Later on, severe pains supervened both in the epigastrium and back. I prescribed some powders of bismuth, magnesia, and extract of belladonna, also some half grain codeine tablets, to be taken if the powders afforded no relief. The appendicular region is still very sore. To continue the ice bags and to eat only milk and eggs while confined to the bed. At 3 a.m. I was called to the telephone. She had taken one powder, fallen asleep, and slept till 2 a.m., when she woke up feeling the pain and took another powder. She was not relieved, and asked what she should do. Directed her to take a glass of warm milk and Vichy (Celestins), if not relieved in ten minutes, to take two codeine tablets.

April 11, 1911. She got along quite well as regards her stomach till two or three days ago, when she drank a glass of wine and ate beef. Since then has again had pain and burning in her stomach. She has marinated, and is tired of salts and the purgative waters. Right half of abdomen still quite sensitive; her corset hurts her. To take one or more of the bismuth, magnesia, and belladonna powders, to loosen her corset, and to paint the appendicular region with tincture of iodine (slightly diluted). For the constipation, a tablet of phenolphthalein every other night.

In the spring of 1912 I met her at a social function. She had fully recovered from her appendicitis, and her stomach was in fine condition.

That a case of gastric disease, without the least evidence or symptom of appendicitis, should not have an appendectomy made merely because it proves refractory to the practitioner in attendance, is so self evident that it would seem unnecessary to make the statement; still, it is but lately that I have had occasion to see two such cases, and the patients were, as was to be expected, as ill after the operation as they had been before. There is no short cut to the cure of gastric ailments. An operation may become necessary to remedy a condition that has developed secondarily, e.g., stenosis of the pylorus after long continued hyperacidity with gastralgic attacks; but only by the avoidance of those factors that have produced the ailment can the patient, operated upon or not, expect to keep his stomach in good condition and himself thereby in good health.

ACUTE RETROPHARYNGEAL ABSCESS.

BY ISADORE HENRY ALEXANDER, A.B., M.D.,

New York,
Otologist and Laryngologist to Governor Hospital, Outpatient Department; Assistant Surgeon, Vanderbilt Clinic, Otology.

AND HELEN MONTAGUE, M.D.,

New York,
Assistant in Nose and Throat Department, Governor Hospital, Outpatient Department.

Acute retropharyngeal abscess is essentially a disease of infancy and childhood; the majority of the cases occurring between the ages of three months and two years. To appreciate why this is so short
a review of the anatomy of the parts is essential. The retropharyngeal space (Gillette) is the seat of a considerable number of lymph nodes. These nodes are intimately connected with the lymph vessels of the tonsils, soft palate, and other soft tissues of the nose, nasopharynx and pharynx. The lymph vessels are in turn connected with the deep cervical glands. Any acute process, as inflammation or infection, affecting the mucous membrane of any of these parts whose lymph channels drain in the way above described, may infect one or more of the lymph nodes situated in the retropharyngeal space, causing it to break down and form an abscess. After the third or fourth year of life these lymph nodes disappear, and therefore we then see considerably fewer cases; rarely they persist until a much later period of life.

Koplik (1) reports a series of seventy-seven cases occurring between the ages of one month and five years, the great majority (forty-one) occurring between the ages of six and twelve months. Our own experience of twenty-three cases certainly sustains Koplik's figures. Of twenty-three cases only one was over four years of age, the great majority (twenty) being under one and one half years of age. Nevertheless, acute retropharyngeal abscesses may occur in adults. Shury (2) of Detroit, quotes R. H. Herrord as reporting a case in a young woman twenty-two years of age, previously healthy. The case went on to spontaneous rupture and the patient was perfectly well again in a few days. Moore reported a case in a man aged forty years and Dunn one in a man aged sixty-two years. E. Delneuville (3) reported a case in a man aged sixty-five years.

The etiology of this disease is sometimes very obscure. Although occurring, as it does, most frequently in the poorly nourished, the tubercular, syphilitic, or rachitic child, it is occasionally met with in children who have previously been perfectly healthy. Tonsillitis, pharyngitis, or any of the acute inflammatory diseases of the nose, mouth, or pharynx may be a predisposing cause. The acute infectious diseases of childhood are sometimes complicated by retropharyngeal abscess. We have seen two cases following scarlet fever. Acute otitis media and acute external otitis (4) have also been mentioned as a cause by Olagna and Santurri of Naples. Foreign bodies in the esophagus are given as a cause by W. Hirose (5). Operative procedures in the nasopharynx or pharynx are likewise mentioned as a cause of acute retropharyngeal abscess. Personally, we have seen two cases following attempted removal of adenoids.

**Symptoms.** The fact that the disease occurs principally in infants unable to talk makes it impossible as a rule to obtain a very complete history. The mother has noticed that for a few days the child has had what she supposed was a cold; was irritable and restless, and had some difficulty in swallowing. When we see the child it has probably been sick three or four days. It usually appears very ill. Face anxious; temperature from 101° to 103° F.; pulse about 130. The respirations are hurried, and with each act of inspiration a peculiar croupy sound is produced. The cough is hard and metallic; with each attempt at coughing the child cries or whines, as if the effort caused pain and suffering. It absolutely refuses to nurse or make any effort at swallowing. Prefers to be carried around; the head is held in a more or less upright position, with the chin drawn forward. The child has a very distressed expression, and every movement of the head seems to increase its suffering. When the abscess becomes large enough to press upon the tissues of the larynx severe dyspnea may ensue, completing a picture of suffering which, once seen, will not be easily forgotten.

An examination of the throat at this time will readily reveal the cause of all these symptoms. When the mouth is opened and the tongue depressed we may sometimes see a bulging forward of the posterior wall; this swelling may be so large as to push forward all the soft tissues of the throat in its immediate vicinity. But many times, with a crying, struggling child, or with a poor light, or, again, when the abscess is situated low down in the pharynx this method of examination is not satisfactory and certainly not to be depended upon. The use of a properly fitting mouth gag and the index finger of the right hand are the only reliable and dependable means for making a thorough examination in these cases. Not only can we feel the fluctuating tumor, but we can at the same time distinguish it from other tumors, such as prominent cervical vertebrae and osteoma; we can also feel any pulsation, if present. A. Sokoloff (6) reported the case of a child aged two years in which he attempted to open a large retropharyngeal abscess when immediately a severe hemorrhage ensued, apparently from one of the large arteries of the neck, and the patient died in ten minutes. At the post mortem examination was found that the source of the hemorrhage was an erosion of the internal carotid artery, and that the cavity of the abscess extended to the base of the skull. Had a proper digital examination been made in this case no doubt pulsation would have been ascertained.

Having made the diagnosis by palpation, the immediate opening of the abscess becomes imperative.

Our method of operating in these cases is as follows: No anesthetic, either general or local, is required. Child is wrapped snugly in a sheet (as for intubation). The nurse (standing) holds the child with the head downward, with its lower extremities over her shoulder. This is done to prevent the swallowing or inspiration of the pus. Inspiration of pus in these cases is followed by a septic pneumonia which is usually fatal. With the nurse holding the child in the position indicated, an assistant introduces the mouth gag. With a central location of the abscess it makes little difference upon which side of the mouth the gag is introduced, but should the bulging be lateral, the gag is introduced on the opposite side of the mouth to allow more room for operation. The operator now introduces his left index finger as a guide, and with the sharp elevator of a Killian subminucous set in his right hand, tears through the abscess wall for about an inch or an inch and a half at its most prominent part. Considerable force is sometimes necessary to penetrate to the abscess cavity with this rather dull instrument. We formerly used a histoury in these cases, but found that the wound closed too rapidly, so that sometimes
of known facts. Our deductions must stand test: First, in the laboratory, as less expensive and errors less likely to kill; second, in the patient, Nature’s laboratory where reactions are called symptoms.

Bacteria grown in the laboratory show modification by variation in culture media. We change a coccos into a bacillus, and vice versa; a toxic into a nontoxic, and vice versa; and by combination of two or more nonpathogens develop pathogenesis, and vice versa, just as Burbank can change the offensive cactus into a valuable food product. This explains the physician the variation in patients, of the same disease, mild or severe; also the natural law in biology: Bacterin, to produce immunity, must be of the same variety and unmodified by culture. So where bacteria grow without great modification in man, or in test tube of ordinary culture media, we can expect to use such cultures of bacterin and count on getting a normal immunity. A good example of this class is the typhoid bacillus, while the pest bacterium is an example of extreme modification by variations in culture media. This explains why the ordinary culture of pest bacteria does not give permanent immunity. Given a culture of typhoid in a tube of culture media, a few day’s growth will saturate this with toxine causing inhibition or apparent death of the bacteria. If separated by filtration or centrifuge, these bacteria will grow if planted in a fresh culture media. Any living active typhoid bacilli placed in such toxine saturated media will show inhibition. This explains the Widal reaction. This filtered toxine free bacteria, if killed without destroying its autolysin or autoferments, will, even in fresh culture media, kill other living bacteria of the same variety before they can develop their full complement of toxine.

Such laboratory finding, culture variation, and autolysis explain:

1. One reason why the world is not a living mass of any one kind of bacteria.
2. Why the saturation of the human system with bacterin causes immunity.
3. Why we kill our bacteria by a temperature of from 55° to 65° C., or other methods to avoid destruction of the essential ferments that aid or teach our tissue to kill bacteria.
4. Why so called antitoxine and toxic bacterial preparation may contain some bacteriolysin through error, and be of some, though uncertain, immunizing value; and a combination of antitoxine and toxic bacterin give an atoxic bacterin. The objection to this is that the foreign serum may irritate.
5. Why bacterial disease, not self limiting, may, by modification, become immunizable by bacterination with autobacterin or modified bacterin. See Neisser coccus modified by extra urethral culture as gonorrhoeal rheumatism; also bacterin coli, extra intestinal modification, causing inflammatory reaction, see systitis and cellulitis, etc.
6. Why bacteria in self limiting diseases, if tamed or modified, can produce only partial immunity except when used alive by inoculation or vaccination with full knowledge that it may at any time, revert to virulence. Such knowledge is one scientific reason why bacterination is preferable to vaccination.

Toxine will cause symptoms in the immune. In-

IMMUNITY BY SCIENTIFIC BACTERINATION VERSUS NATURAL IMMUNIZATION IN SELF LIMITING DISEASES OF BACTERIAL ORIGIN.

By C. G. ROEHR, M. D.,

Fort Pierce, Fla.

The study of biology, including bacteriology, has given us the science of preventive medicine. This out ranks, in importance to man, the effect of the gas engine with its automobile and flying machine, or the dynamo with its wireless.

Immunity, as a term in general use, is in definite and may mean anything from a thick dry skin, to keep out bacteria, to a trained brain that can avoid excess, unhygienic conditions, or exposure to infection. In this special class of diseases, it means the power in our tissue to kill the cause of such disease, in contradistinction to the term susceptibility, which means the power of such disease element to grow in or kill us. Such power of protection or resistance is called immunity. We are directly interested in this bactericidal protective power as resulting from or caused by the saturation with the autolytic or autoferment properties of such special varieties of bacteria.

Our effort to-day is to explain why it is preferable to gain such protection immunity by bacterination without symptoms of disease, instead of the natural method of saturation by disease, with its danger of toxic action and sequel, called survival of the fittest. We study biological laws by analysis
fection in the mother may cause toxic milk; so tox-
ine symptoms do not always prove infection. Tox-
ine does not immunize. All symptoms including
action and reaction in bacterial disease are a result
of the toxine only. All tests depending on toxine,
toxic inhibition, or toxic complement reaction are
liable to modification in not less than twenty per-
cent. of cases. This uncertainty wipes out scientific
reliability for diagnostic purposes. Toxine inhibits
bacteria, making phagocytosis of living bacteria pos-
sible, and explains immunization by infection—bac-
terium will grow in autotoxin pure or alytic. Bac-
terin, toxine free, will not cause reaction unless the
system is infected by this identical variety of bac-
teria.

This knowledge is of extreme value to the diag-
nostician on account of this positive scientific result,
and is commonly known now as a test for tubercu-
losis with tuberculin and as a test for syphilis with
luetin. It may be well here to refer to the fact that
two or more so called nonpathogenic varieties of
bacteria may in combination become pathogenic.
This might require a combined bacterin for diag-
osis, and is one explanation of the value of a mixed
autobacterin treatment. The term bacterin, as we
use it, means the unmodified culture of the same va-
toxine freed, killed in such manner as to retain
its bacteriolysis or ferment. Therefore, all self limi-
ting bacterial disease
1. Can be diagnosed by bacterin;
2. Can be prevented by bacterination;
3. Can be cured by bacterination.

This last statement, it is to be understood, does
not necessarily include repair of injury already re-
sulting from the toxine. Here we use antitoxine to
prevent injury or death until bacterination can cause
immunity. Anaphylaxis is our index for the dosage
of bacterin during infection, and, although pneumo-
coccus immunity is only temporary, pneumococcus
bacterin is of great value. A digression is justifiable
here, to remark that as infection in man is seldom or
never of one variety only, it would be advisable to
use a pure bacterin for prevention and a mixed bac-
terin for treatment. Bacteria carriers are a result
of increased bacterial resistance or modified bacteria;
or if interference with circulation by the wall re-
sulting from toxic irritation. They will be cured by
excess immunity, made possible through bacterina-
tion excess. Only one or two per cent, will require
surgical aid to drain or increase bactericidal blood
supply.

We know that the experiments in yellow fever,
malaria, typhoid, etc., have been made possible only
by the voluntary sacrifice of the noblest men in our
profession. We honor them—but why not use the
condemned criminal for our biological study? Mod-
ified bacterin inoculation for tuberculosis and syph-
ilis were experimented with years ago in France,
and finally prohibited by law as dangerous.

METHODS NOW IN USE FOR LOCAL AUTOBACTERINA-
tion.

Heat.

Steam infected uterus.
Hot water irrigation—infected wounds.
Poultice—Convenient and cheap.

Sun glass—in pressure anemia to favor penetrat-
one of heat. Can we focus x ray or radium or
helium ray with sun glass? No.

Cold.
Ether or ethyl spray.
Liquid air.
Ice bag or pack.
CO₂ pencil.

Chemicals—Electricity.
X ray, ultraviolet ray, radium ray.

BACTERIAL DISEASE CLASSES.

Self Limiting Permanent Immunity.
Smallpox: scarlet fever; measles; whooping
fever, mumps; pest or plague; Asiatic cholera; ty-
phoid fever; boils or pimples, poliomyelitis; cere-
bospinal meningitis.

Self Limiting Temporary Immunity.
Pneumonia (Diplococcus lanceolatus), la grippe.
Erysipelas.

Racial or Partial Immunity.
Tuberculosis, leprosy, gonorrhea.

(Autoinoculable to the individual.)

GELATIN AND OLIVE OIL IN THE
LIBERAL DIET OF TYPHOID FEVER.

By Israel Bram, M.D.,
Philadelphia.

In the very near future a strict milk dietary of
the sufferer from typhoid fever will be looked
upon with disdain as an antiquated, cruel, and even
harmful method of procedure. Time, reason, ex-
periment, and experience are responsible for chang-
ing the views and theories of medical men in the
management of disease. Only a few years ago it
was considered dangerous to administer a drink
of water to a sufferer from fever, whose anxious
expression and parched lips bespoke intense suffer-
ing from thirst, and whose organs were pitifully
begging for nature's cooling draught. During
those days the higher the temperature of the pa-
ient, the more he was deprived of fresh air; and
it was considered criminal to ventilate the chamber
of the sufferer from croupous pneumonia.

But times have changed, and so has the mortality
from the various acute febrile diseases. We quench
the thirst of a poor mortal with all the H2O he can take; we admit a liberal quantity of fresh air to reoxygenate his blood; and if perchance the patient suffer with a condition characterized by pulmonary embarrassment, we place him on the roof, even though the atmospheric temperature be zero. And so in typhoid fever it will soon be discovered that a milk diet is usually harmful for the following reasons: (a) Many patients possess a natural aversion to milk; (b) it in time becomes monotonous to nearly every patient; (c) it is not really a "complete" food for adults, which fact assists the process of emaciation already being carried on by the existing toxemia, thereby reducing the patient's resistance to a minimum; (d) hard, cheesy curds resulting from the ingestion of milk are largely responsible for the irritation of the gastrointestinal mucosa, fermentative processes, tympanites, and even intestinal hemorrhage and perforation; (e) a prolonged milk diet renders the digestive processes so delicate as to lessen their ability to digest other foods for many weeks. This last factor explains why typhoid patients under a milk diet, when given more liberal feeding at any time during the course of the disease, fare badly, and oftentimes promptly present evidences of tympanites, sometimes leading to hemorrhage and perforation. On the other hand, it has been proved by many clinicians that patients fed liberally from the very onset of the disease fare much better than those on a milk diet.

It is necessary to employ five quarts of milk daily in order to furnish a sufficient number of calories to maintain the patient's nutrition. This quantity of milk is practically impossible for a person in health or disease, so that if the milk diet is insisted upon, the patient is slowly starved while combating a prolonged infection, during which his resistance and nutrition should be safeguarded in order to enhance prompt convalescence and recovery. Careful studies by clinicians in this country, including the consideration of twenty-six patients of my own, prove undoubtedly that the typical typhoid patient can cope very well with the ordinary proteins, carbohydrates, and fats with slight modification in their various preparations, and with especial preference for raw or soft boiled eggs, butter, and crackers, buttermilk, milk toast, junket, beef tea, scraped beef, cup custard, oatmeal, well boiled rice, gelatin, and olive oil.

The paper by Johnson and Watt entitled Typhoid Fever. Its Milk Free Treatment (New York Medical Journal, February 1, 1913) prompts me to make these remarks concerning gelatin and olive oil, with conclusions derived from the treatment of the beforedementioned twenty-six patients who had suffered with this disease and who made prompt recovery, without complications, relapses, or any appreciable emaciation. Johnson and Watt call attention to the manifold virtues of gelatin in the treatment of typhoid fever, urging that it be administered continuously during the course of the disease (excepting in the presence of thrombosis). As a matter of fact, my experiences with gelatin in this disease as a food, a prophylactic, and a remedial agent in the treatment of intestinal hemorrhage, were outlined in a short paper in the Dietetic and Hygienic Gazette of June, 1911, in which it was shown that the use of gelatin in typhoid fever is almost imperative in view of the numerous indications for it which arise. Moderate quantities of gelatin administered to these patients tend strongly to the prevention of intestinal hemorrhage. This seems to have been overlooked by the profession at large. It has been universally conceded that gelatin possesses hemostatic properties, and if this be true, it should be administered to all patients suffering with conditions in which hemorrhage may occur as a symptom or complication. Furthermore, gelatin possesses nutritive properties simulating the proteins, as well as serving to assist in overcoming the monotony of the same in the diet. Therefore in a measure it aids in the prevention of the starvation to which the enteric patient is usually subjected.

Pure gelatin is usually nearly colorless, odorless, and tasteless. The easily prepared gelatin on the market are often colored and flavored with chemical substances injurious to the economy, e.g., sulphuric acid, sodium benzoate, etc., and should be avoided. It should be made from government inspected calves' feet, treated with pure boiling water, and then delicately flavored with pure light wine or lemon.

In the Medical Review of Reviews, September, 1912, I pointed out that olive oil has a broad field of usefulness in typhoid fever and should be employed throughout the course of the disease. As a food administered in doses of from one to three ounces, three times a day, it is a valuable adjuvant to the diet. It not only assists in overcoming the tendency to emaciation, but in many cases the patients show a gain in weight during convalescence over and above the weight possessed by them before the onset of the disease. As a laxative, olive oil has no equal in typhoid fever. By its bland soothing influence it permits the intestinal contents to escape without irritating the inflamed Peyer's patches. In this way the tendency to intestinal hemorrhage is diminished. The intestine, kept clean and free from gas forming elements by this oil, is practically never distended, and thus, in the absence of tympanites, we have little fear of intestinal perforation. A high rectal injection of lukewarm olive oil as occasion demands is also very gratifying to these patients.

In conclusion, I would remark that I have noticed no untoward results from the free use of gelatin and olive oil in typhoid fever. I would therefore urge that these substances be added to the routine dietetic of this disease.

1714 North Seventh Street.

Treatment of Whooping Cough.—Renigio, in Lyon médical, April 27, 1913, is credited with the advice to place in various parts of the sick room four or five grammes (one drachm to seventy-five minims) of the following mixture:

Methyl salicylate, ....................... 2 parts;
Eucalyptol, ............................. 1 part.

This should be done twice during the daytime and also once in the evening.
EFFICIENCY AND HEALTH.

By Samuel Horton Brown, M.D.,
Philadelphia.

The keynote of nearly every essay appearing in the popular magazines of the day is efficiency. We are kept informed how to become a foreman, how a better foreman becomes a better superintendent; and also that if the new superintendent does not show himself to be of much greater capacity than the previous incumbent, he is replaced by another. But if he follows the advice prescribed by this or that essayist, he is certain to fill the chair of the first vice-president, who "is getting old and expresses it through his ultraconservative views about everything." And so on, ad nauseam. Now, what becomes of the inefficient? This is probably being saved for the Christmas numbers to come, when the families of the efficient will carry Christmas baskets to the wives and children of the inefficient members of the community.

The question arises as to what extent have we taken, and must we take, this "efficiency propaganda" seriously. The inefficient are still managing to drag out a fairly comfortable existence, comparatively few are in the poorhouses and jails—there are not enough such institutions to hold them all! There do not seem to be sufficient drawbacks in "inefficiency" to discourage it as we would like, nor on the other hand, are there, apparently, enough compensations in "efficiency" to encourage a man to work himself to death to acquire the approbation and regard of the essayists of the beforementioned magazines. Really, after all, the greatest return to the efficient is the satisfaction of work well done.

In order to take a strictly nonpartisan view of the situation as it actually exists, we must first try to seek for ourselves the real disadvantages and advantages connected with either condition. The essayists assume that man is a collection of numerals which by skilful manipulation may be doubled, trebled, quadrupled, etc., to an infinite degree, whereas we know that man in a state of perfect health has a reasonable expectation of just so many years. His earning capacity cannot be counted upon until he has passed fourteen of these years, and from then on to thirty-five it will depend upon his special training and physical endurance. After thirty-five his work will be done largely by his head, as we well know, from the experience of athletes and athletic instructors, that man is past the zenith of his physical career at that time. From then on, for practical purposes, we find a static condition of affairs for about twenty years, and then an imperceptible decline, until he hears his call. Your popular magazines admit no such contingency, in the event of careful adherence to its directions. This is the picture of the healthy average man. It is reasonable to assume he has been fairly happy.

Supposing, for instance, he had displayed an average degree of inefficiency, what would have been the result? Would it bring any especial calamity upon him as an individual? The most biased person of experience will fail to find any reason to believe that it would. A healthy man can always find a job, and always manage to support himself, even though his training be limited and his independence overthrown. His greatest damage is not to himself, but to those about him, and as he has little interest in others, it is unlikely that any well written literary efforts are going to bring him up to the standard. His first bad effect is going to be felt by his fellow workers who are likely to be injured, perhaps maimed for life, by his ignorance, stupidity, and carelessness. In this way a large expense is unjustly thrown upon the shoulders of the innocent, perhaps those of the standard efficient class. There is no argument for efficiency to offset this. There is every reason to assume that a man of this inefficient class will follow the law of averages and probabilities, just as does the efficient man, and become a man of family. Here is where the real trouble starts, and the rest of the story is to be read in the reports of the Juvenile Court, the Children's Aid Society, the Society for the Prevention of Cruelty to Children, the day nurseries, the social service organizations, and eventually the police court and the so called Tenderloin.

Incidentally, it may be remarked that, while many investigators have tried to prove that no girl can live decently on less than six dollars per week, they have failed to make the point clear that all fallen women, with very few exceptions, have come from homes that were homes in name only—the product of inefficient parentage. Poverty is not always avoidable, and a girl from a good home with good hope training seldom if ever goes bad perpetually. The report of the Chicago Vice Commission will bear out this statement. It becomes obvious immediately that this is most expensive to the community, and that this expense must be borne by a part of the community not at all at fault in the matter, but in order to protect it from worse and greater evils, mostly disease. This is scarcely an incentive to efficiency, for the inefficient have little to lose; the Declaration of Independence and the Fourteenth Amendment protect them from any great infringements upon their individual rights. Somehow, something always turns up for them if they can count upon a redeeming virtue, a little patience.

Now, in order to hold your attention, we have referred to a healthy adult as an inefficient. This is a great rarity. Inefficiency and ill health are interchangeable factors similar to conjugate foci in optics. The healthy man is anxious to work, and usually finds a way to obtain it in order to carry out his obligations to his family and himself. No matter how ignorant he may be, nor what cramped and narrow views of political economy he may hold, he inclines to the best form of citizenship by his care of the units entrusted to him. The man endowed with good health at the start is nearly always "come back" after the ordinary indiscretions of youth. The man with poor physique or poor health, whether congenital or acquired, may in rare instances by the cultivation of some one talent to the extreme attain great heights by reason of his genius, as is evidenced by the lives of Byron, De Quincy, Carlyle, Poe, Paul I. Cicero, Ford, Pulitzer, and others; but it is questionable whether any of these have fulfilled the highest ideals of the normal average man.
In a novel written a few years ago by William J. Locke, entitled “The Beloved Vagabond,” the author endows his principal character, Paragot, with a genius for architecture, while, together with this the man is possessed of a most marvelous range of education and a philosophy and wit which are very attractive to the reader. He drifts about the Latin Quarter in Paris and similar places in other cities, making friends and also inebriates among the riff-raff of the artistic colonies, but none among the ordinary well behaved citizens. A drunkard himself, but able to keep his mind clear through it all; dirty and unkempt at all times, he ultimately sees the light in the person of his stout, rugged, uneducated, inartistic, peasant girl protégée, Blanquette, whom he marries, and with whom he goes into the country and finds the philosopher’s stone in the peaceful life of a family and a farm. The man in this instance was lost to himself until the ordinary average basis of life was impressed upon him, and his inefficiency could be readily traced to his inebriety; but his drinking would never have reached inebriety had his inherited temperament been average, or had his food been as regular as a day laborer’s.

Therefore return to the original proposition of ill health or faulty constitution or physique as a basis of inefficiency, and as physicians we have little difficulty in demonstrating it to our own satisfaction. Starting at the very beginning, there is scarcely any need of reminding you of the expense and inconvenience attendant upon a maternity case. Even the most normal case is a great inconvenience to every one, physician included, no matter what the social or financial condition of the patient may be. Among the poorer people it is disproportionately greater, and the poorer the family the greater the number of children as a rule, and the greater the complications. The additional drain upon the family’s resources will certainly be felt eventually, and usually when it can least be resisted. The father, the mother, or the children, which ever is the weakest component, ultimately succumbs to circumstances. In the case of the father this is manifested by a less satisfactory performance of his daily work, a shift of jobs, retirement, nervous breakdown, possibly tuberculosis; in the case of the mother, all sorts of gynecological conditions, operations, etc.; in the case of the children, all sorts of dietetic disturbances, marasmus, starvation, dissolution, etc. In any event the survivors are far below par, and are expected, in this more or less “crippled” condition, to cope with difficulties that have called forth the best efforts of the most healthy. Death in a poor family is a terrible economic misfortune, apart from any other consideration. Even in the presence of insurance, the expense lays an obligation upon the survivors that often takes months and frequently years to satisfy. In the case of the child, to have lived to maturity would have been less expensive, since the expense is more evenly divided, and there is always a possibility of a return in the wages of the child.

Is it, then, any great wonder that we encounter in the schools and homes such a great proportion of defective of all grades, when we stop to consider the seed and the soil from which they spring! Do not these represent the bulk of inefficient, rather than those who just do not care about working? These cases are the ones, at least, that come to our knowledge as physicians and are definite, tangible, demonstrable defectives. Those of you who are interested in school inspection work in the congested districts of the city are doubtless impressed by two things: first, the isolated instances of exceptional brilliancy, often surpassing children of the same age and grade in other portions of the city, and, on the other hand, the overwhelming proportion of children who require help of some kind, varying from a pair of glasses and a seat near the blackboard to the skilled attention of the backward school.

The first instance, while it may cause the chests of the fond parents to swell with pride, is as much of a disease as the latter. Precocity is as abnormal as chorea; in fact, the two may be considered analogous. The centres of inhibition for motor impulses are held in abeyance in the case of chorea, while in precocity the psychic impulses are given free rein. The subsequent histories of such children show that while they may develop some talent to the extreme, on the whole they lack the average qualifications, and in the long run cost the community as much as do the other children, oftentimes more. The other large group of children may belong to the tonsil and adenoid class. The definite views on the remote effects of enlarged tonsils and adenoids held by those who see most of them are much in vogue, and time alone can test the accuracy of these views. Personally, it would seem to me that these lymphoid structures become enlarged to ward off infections, and not as the result of pure “cussedness”; and I would hesitate to remove any that were not causing positive serious obstruction to breathing. But then I am not an otolaryngologist, and, on the other hand, I do not suppose they would put glasses on so many people as I do. At present this necessarily causes a great interference with the school work and brings expense to the several departments concerned, and must deprive the child of a large part of its education. Any operation on a child is a shock to its highly sensitized immature nervous system and is certain to be followed with results that temporarily impair its reception of impressions properly. Yet we are in duty bound to give the child this advantage until it has been definitely proved to be otherwise.

At the same time, or in others of the same grade, we find tremendous defects of vision. Nearly every child in the downtown schools has some such defect. It may be very small and negligible in the lower classes, but, as many of you have noted, it increases in the higher grades, becoming quite pronounced if still disregarded. To those of you who have worked in the eye clinic of Mt. Sinai and other hospitals downtown, deficient vision in the school child is a very timeworn topic. To the up to date reader of medical literature, those who follow the publications from week to week and month to month, the relation of all sorts of neurological phenomena to eyestrain is equally ancient. But the relation of deficient vision in the school child to sociology and political economy has as yet been given only the most superficial attention. Education, whether manual, academic, or of whatever
PRIZE ESSAYS.

THE TREATMENT OF BURNS.

BY JOSEPH V. KLAUDER, M.D.
Philadelphia.

Treatment depends upon the degree, the extent, and the stages of the burn. In all burns the Snedec open method of treatment at the appropriate stage is advocated, in which occlusive dressings are eliminated and strict cleanliness and good drainage are carried out, and combined with heliotherapy.

Depending upon the severity, as will be given, hydrotherapy is especially advocated, as well as hot sweat packs, steamed blankets, or the electric light pack.

Since the results are about the same clinically in burns resulting from contact with dry heat, acids or caustics, and scalds from hot liquids or steam, the treatment in a general way, excluding the neutralization of the caustics, is the same.

Burns of the first degree, of very small involvement, require no treatment excepting dusting with bland powders, such as stearate zinc or zinc oxide powder, and lotions of bicarbonate of soda solution or aluminum acetate solution, after first being cleansed with sterile normal saline solution, hydrogen peroxide, or tincture of green soap; adherent matter or home made remedies may be removed with sterile olive oil, alcohol, or benzine, depending upon the nature of the foreign material.

This same cleansing should be carried out in all burns, providing the condition of the patient permits, if too much time is not lost, except where there is large or extensive and severe burns.

The diagnosis is not easily made. It is usually made as fatal from burned areas involving more than two thirds, and often when more than one third. Comparatively small areas may result fatally, especially in children. It is grave, regardless of the degree, if involvement is one third or more of the body in adults, and about one ninth in a child, owing to the disproportion between body weight and skin surface. If there is the slightest doubt as to the prognosis the case should be treated as a severe one. In regard to the second and third degree burns, make a basal incision and evacuate the blebs in second degree burns; in third degree burns remove all necrotic fragments of tissue and clothing. In both degrees, if the lesion is a local one, treatment should be carried out on general surgical principles—local disinfection, drainage and removal of sloughing material. In regard to local treatment in the severe burns of both degrees, it becomes of subsidiary importance, nor is it a matter of great importance, which of the usual therapeutic agents are used. There is a mass of accumulative experimental evidence to show that death following burns is due to an autointoxication. According to the intoxication theory, the poison may be formed in the blood, in the skin, or may be a result of a change in metabolism, its presence being shown by the increased toxicity of the urine, as shown by Reiss, who has proved that the urine of burned patients is poisonous and causes the same symptoms as the burn itself. Klebs, from his experiments on rabbits, assumes the formation of a poison in the blood. Parabiosis experiments, recently performed, prove that the toxic substance is not a blood poison, but does not exclude the blood as a source of the poison. Burkhard found that the hemolysis occurring in the blood is a consequence of direct heat action upon the erythrocytes. Pfeiffer and Parascandro both arrived at the conclusion from their experiments that the toxin produced is a cytotoxic closely related to snake poison and nucleo-

PRIZE QUESTION CXXXV.

THE TREATMENT OF BURNS.

BY JOSEPH V. KLAUDER, M.D.
Philadelphia.

Questions for discussion in this department are announced at frequent intervals. So far as they have been decided upon, the further questions are as follows:

CXXXVI.-How do you treat cholera infantum? (Closed July 15th.)

CXXXVII.-How do you treat threatened abortion? (Answers due not later than August 15th.)

CXXXVIII.-How do you treat insomnia? (Answers due not later than September 15th.)

CXXXIX.-How do you treat chancroid? (Answers due not later than October 15th.)

Whoever answers one of these questions in the manner most satisfactory to the editor and his advisers will receive a prize of $25. No importance whatever will be attached to literary style, but the award will be based solely on the value of the substance of the answer. It is requested (but not required) that the answers be short, if practicable no one answer to contain more than six hundred words; and our friends are urged to write on one side of the paper only.

All persons will be entitled to compete for the prize, whether subscribers or not. This prize will not be awarded to any one person more than once within one year. Every answer must be accompanied by the writer's full name and address, both of which we must be at liberty to publish. All papers contributed become the property of the JOURNAL. Our readers are asked to suggest topics for discussion.

The prize of $25 for the best essay submitted in answer to Question CXXXV has been awarded to Dr. Joseph V. Klauder, of Philadelphia, whose article appears below.

1901 Mt. Vernon Street.
proteids. According to Wilms and Spieglcr, the toxine is one of the byproducts of overheated albumin. The exact nature of the toxine with which we are dealing has not been determined.

From the basis of treatment then we are dealing with an autointoxication, in which there is evidence to show that it can be combated by any local application; the latter is of importance later, and is governed by the surgical principles underlying the treatment of any similar surgical condition of necrotic sloughing area, and still later, granulating and healing surface.

The indications for treatment are: Treat the shock, which does not occur any oftener in burns than in other grave injuries. Treat the burned areas aseptically and surgically, and, at first, from a standpoint of shock. Combat the autointoxication. Treat the conditions arising during convalescence. In a severe burn, when the patient is first seen, too much time should not be lost in local treatment, or in a too thorough or prolonged cleansing at this time. Infection in burns plays but a small part in the final result. Again, the area is an open one, and drainage and appropriate treatment can readily be established later.

Our attention, in treatment, should be directed primarily to the shock, as the maximum of two evils; our attention can be directed to the burned area later. The patient is given morphia for pain, and is stimulated at appropriate intervals by atropine, strychnine, camphorated oil, caffeine, or digitals. He is placed on a bed between blankets, surrounded by hot water bottles, the foot of the bed elevated, autotransfusion practised if possible, and a pint of saline solution, containing adrenalin, is administered intravenously or by hypodermoclysis or enteroclysis. Throughout the stage of shock continuous enteroclysis is given.

From the standpoint of shock, I do not place the patient in a saline bath, or apply saline solution locally on the burns, as I do not believe reaction from shock is favored by having the patient surrounded with wet dressings. Consistent with the shocked condition of the patient, I cleanse the areas hastily, or not at all if they are fairly clean, and apply boric ointment and sterile dressings, for their soothing and protective effects, and the minimizing of heat radiation. Oxygen is administered, preferably through the pulmator, for the good it may do, in the way of repairing any damage sustained by the blood. After the reaction from shock, stimulation is continued if necessary. Potassium citrate, ten to twenty grains every four hours or so, is given for its diuretic effect, and a milk diet of sufficient caloric value. Large quantities of water are given by mouth. Normal saline, up to four litres daily, is administered subcutaneously or per rectum. The bowels must be kept freely open. At this stage, as shown clinically and by necropsy, acute parenchymatous nephritis is always present and active elimination is our aim. Skin elimination is favored by keeping the patient warm and between blankets. Hot sweats are advocated, preferably by means of the electric pack, which is placed over the uninvolved regions or even the whole body, the burned area being covered by sterile dressings. I have given these packs in high temperatures with no harmful effects. The state of the circulation is watched, if possible the patient is sweated about twenty minutes once or twice a day. Hot enemas precede the pack, and the patient is kept warm by the application of external heat. The treatment is continued during the stage of intoxication the first four to six days. If the hot pack is not applicable on account of the patient's low condition, I use normal saline or bichlorate of soda baths at a temperature of 100° F., the patient remaining in the bath about a half hour or longer, once or twice a day; these baths always supplant the hot packs later on, and are given occasionally during the first six days, mostly for their cleansing effect. They are sedative and soothing to the patient, eliminative, stimulative, relieving the internal congestion of organs by directing the blood toward the skin; they are cleansing and retard suppuration, prevent absorption, favor nutrition and healing processes in the skin, and augment the heat withdrawal.

As early as possible, I use the open method of treatment. The areas are left undressed, being protected by cradles covered by blankets; all necrotic and sloughing material is cut or flushed away. Cleansed with peroxide, sterile normal saline or bichlorate solution, and dusted with stearate of zinc or thymol iodide, all crusts or hardened necrotic material being softened with boric ointment spread on gauze; on removing the latter, the former is usually adherent or easily removed. The lesions are then exposed to the direct rays of the sun one hour or more daily. Early skin grafts by Thiersch's method, or amniotic membrane, are applied; the latter I have used with fair results. Scarlet red ointment may be applied to the margins to stimulate the regeneration of the skin; I have used it with good results.

The parts involved should be subjected to passive motions early, and attention paid to posture, to prevent deformities resulting from cicatrizes. Hygienic and dietetic treatment should be carried out. The patient should now be well nourished, with due attention paid to his damaged kidneys. The anemia should be combated with iron and tonics. With appropriate treatment meet all complications as they may arise.

The mortality of burns under the new form of treatment has decreased. Mention may appropriately be made, particularly of one case, of a third degree burn of the entire chest anteriorly and laterally, and a small portion of the upper abdomen, the anterior and lateral portions of the neck and the entire scalp. The patient, an adult, was burned about four months ago; recovery has taken place.

**Episcopal Hospital, Philadelphia, Pa.**

**Dr. Frank K. Boland, of Atlanta, Ga., states:**

Pain, infection, and shock are the principal conditions to be met in the treatment of burns. In a bad case nothing is better for pain and shock than morphine hypodermically. Other means of preventing shock, such as keeping the patient warm and the administration of stimulants, must be used when necessary. In any except very mild cases the patient should be put to bed, and the diet, bowels, and kidneys given attention. For the treat-
ment of ordinary burns I have found nothing so good as a one per cent. aqueous solution of picric acid. It is mildly antiseptic and relieves pain better than any other application. Its discoloration of the skin and clothing is its only objection.

To meet emergencies I always carry in my satchel several powders containing seventy-five grains each of picric acid, kept in a tightly stoppered bottle. One of these powders, dissolved in a pint of boiled water, gives approximately a one per cent. sterile solution. Since cases of poisoning have been reported from the use of this drug (though I have never seen one), if the burn covers a very wide area I use a weaker strength. After half of the first pint has been used I generally fill the bottle with sterile water and then on employ a solution of about one half of one per cent.

The burned area is first washed as clean as possible with normal salt solution, which causes much less pain than plain water. The picric acid solution is applied on sterile gauze or lint, never on cotton, and loosely bandaged. Too much thickness should not be used, because the dressing is to be kept continuously moist. The dressing should be changed only as often as cleanliness requires, probably every twenty-four or forty-eight hours at first, and then less frequently. Remove very gently, moistening with saline solution. Blebs should be opened with a sterile instrument, but otherwise left undisturbed.

In small burns I have frequently continued this dressing until healing was complete, but if the burned area is large, when granulation begins I usually apply sterile petrolatum or ten per cent. boric acid ointment. If granulation is slow, or becomes exuberant, I apply nitrate of silver solution as strongly as compatible with the comfort of the patient, the pure stick preferably. I have always found silver nitrate better than balsam of Peru or scarlet salve.

Should the burned area cover a flexor surface, such as the front of the elbow or the palm, the danger of contraction must be thought of, and antagonized by suitable splints. A light splint gives much support in any extensive burn of the forearm. Where adjacent fingers or toes are involved, they must of course be kept separated, to prevent adhesions.

If the burn is very dirty, or infection is feared, it is best to anesthetize the patient and scrub and asepticize the wound thoroughly. Antitetic serum must not be forgotten in such cases. Anesthesia is especially indicated in burns of the scalp, where shaving is necessary.

In burns covering a large proportion of the surface of the body, on several occasions I have abandoned all dressings and placed the patient in a bathtub containing a warm weak solution of sodium bicarbonate. The patient can be made comfortable and thus treated for several days. The prognosis in such cases is generally bad, but the agony of the change of dressings is done away with.

Next to picric acid I prefer some other moist dressing, such as normal saline or ten per cent. boric acid. Ointments and oils are not so clean and do not absorb discharges. A moist dressing must always be kept moist. The main thing always is to avoid infection. Skin grafting must not be done too soon, unless contractions are feared. Many apparently hopeless raw areas, especially in the young, will heal if proper treatment is kept up.

Dr. Louis R. Brager, of New York, remarks:

Burns, as we all know, are classified according to their degree, each with their characteristic train of symptoms, and each requiring treatment consistent with the degree of burn and extent of area involved.

In burns of the first degree, with its erythema and heat persisting for hours or days, followed by some degree of desquamation, and an amount of discomfort depending upon the extent of the area involved, the patient should be made comfortable by the early application of an alkali, as sodium bicarbonate, or borax, best in solution and used in the form of a cold compress, until the inflammation has been controlled. In from six to twelve hours the application of some mild ointment, as boracic acid or zinc oxide, in ten per cent. strength, will be all that is necessary to control and cure the condition. We must keep in mind the fact that very extensive burns even of the first degree may be attended by fatal shock.

In burns of the second degree, we have an inflammation of the skin, with vesication. Here large and small blebs filled with clear, and later with cloudy serum, form on the skin at once, or after several hours. The constitutional effect in this degree of burn depends upon the size of area involved. The area should be thoroughly cleansed and the vesicles punctured with a sterile needle to allow the serum to flow out, but the pellicle should not be removed, but simply allowed to drop on the moist, red sensitive true skin beneath. The application of a one per cent. watery solution of picric acid as a wet compress, or the use of a five per cent. picric acid ointment, is beneficial. This relieves the pain, prevents suppuration, lessens the discharge, and lessens frequency of the dressings, which are always painful. Ointments of boracic acid or zinc oxide, in ten per cent. strength, are recommended. Where picric acid is employed the patients should be watched, as absorption of this drug frequently produces an albuminuria.

Where the patient has a rise of temperature, the part affected should be treated with a mild wet antiseptic dressing preferably, as solution aluminum acetatis, Thielsch's solution, boracic acid solution, salt solution, hydrogen peroxide, etc., and later followed by the mild ointments. If the area involved is extensive, the patient is usually in a condition of shock, and this must be overcome at once by the hypodermic use of morphine, grain 1/4, and atropine, grain, 1/120, repeated frequently, if necessary. Then stimulation with strychnine, camphor, whiskey, and other supportive measures described in detail later. When the shock has been overcome, the entire area should be cleansed and treated as above described. Fingers and toes, when burnt, should be separated by wet pieces of gauze or lint, so as to prevent webbing. In this degree of burn there is no scar formation, but frequently a smooth pigmented surface remains.
In burns of the third degree, under which head are included all burns involving actual destruction of skin and subjacent tissues to varying degrees, up to complete charring of the parts. Much of the subsequent scarring and deformity results not from the primary injury, but from consecutive sloughing and gangrene, and contraction of the new formed tissue during and after healing. These patients are always in a condition of shock, and treatment must be active.

Give hypodermic injection of morphine, grain \( \frac{1}{4} \), and atropine, grain, 1/120, frequently repeated. Stimulants are indicated as strychnine, grain 1/30 to 1/20, camphor in sterile oil, ether, whiskey, given hypodermically. Epinephrin, using one drachm of a 1/1,000 solution to a pint of normal saline solution, may be given intravenously in extreme cases. The temperature being subnormal, the patient should be wrapped in hot blankets to maintain and add to the body heat. Hot saline enemas, or hot coffee, by the bowel, are excellent.

After he has reacted from shock, it is advisable to give the patient an anesthetic, and remove all the sloughing tissue, so as to produce quick healing and leave as little deformity as possible. If the patient cannot withstand an anesthetic, this can be done under morphine, for the patient must be protected from pain.

In babies, shock may be overcome by giving the patient a warm alkaline bath. Shock is usually followed by a reactionary fever due to sepsis, from absorption of necrotic tissue. If this reaction is excessive, it results in inflammatory processes elsewhere in the body, from which these patients usually die.

Ulcerations following burns of this degree are at first treated with mild wet antiseptic dressings, and later stronger ointments may be used, as iodihol ointment, or balsam of Peru and castor oil in equal parts. Picric acid should not be used here, as absorption will take place and poison result. When granulations form the skin edge should be protected with rubber tissue. If granulation is slow stimulate it by touching up the area with silver nitrate or copper sulphate in mild solutions. Exuberant granulations require burning down with pure silver nitrate. If healing is slow, or the area involved is extensive, skin grafting is advisable. This should be done early, so as to limit the formation of scar tissue.

When burns begin to heal, if deep, they heal with a degree of scar tissue which is greater than any other healing process in the body. All burns in the region of joints should be treated on splints to avoid contractures, although this is often most difficult to accomplish. Secondary plastic operations are sometimes done after severe burns.

In first degree burns extending over a large area, and in burns of second and third degrees, the urine should be examined daily for signs of nephritis. Potassium citrate, twenty grains, with spirit of nitrous ether, twenty minims, in plenty of water, should be given three times a day. Free action of the liver, kidneys, and bowels must be maintained. When an extremity has been carbonized, amputation must be performed. In severe burns of the head there is a strong tendency to inflammation of the brain, in burns of the chest to inflammation of lungs, in burns of abdomen to inflammation of abdominal organs; inflammation and ulcer of the duodenum may follow any burn. These patients usually die when such complication sets in, consequently treatment must be active to avoid such complications, for when they occur treatment is of not much avail.

Summary.—Treatment is local and constitutional.

First Degree—Rest to the part, application of wet compresses of sodium bicarbonate, or of boric acid, followed in a few hours by the application of boric acid ointment or zinc oxide ointment, ten per cent. In extensive burns treat shock with morphine and atropine, then stimulate with strychnine, camphor and whiskey. Treat locally, as stated.

Second Degree—Clean area with antiseptic solution, open vesicles by puncture, apply picric acid in one per cent. watery solution, or five per cent. ointment. If fever be present apply wet antiseptic dressing—Burrow’s solution, Thiersch’s solution, boric acid solution, salt solution, or peroxide of hydrogen. Later use mild ointments—boric acid, or zinc oxide in ten per cent. strength. Treat shock, if pre-existent in extensive burn, with morphine, grain \( \frac{1}{4} \); atropine, grain 1/120; use hot blankets to maintain body heat; give strychnine, grain 1/30 to 1/20; camphor, whiskey, ether, epinephrin (one in 1,000); and hot rectal enemas. The fingers and toes to be separated with wet lint to prevent webbing; watch kidneys for nephritis. Liver, kidneys, and bowels to be kept active. During convalescence give plenty of food, fresh air and exercise. Use iron as a tonic.

Third Degree—Treat shock as described above. Anesthetize or put patient under influence of morphine on account of pain and remove charred flesh as quickly as possible; apply wet antiseptic dressings, as in second degree burns. Later use stronger stimulating ointments—iodihol, or balsam Peru in castor oil (equal parts). Charred extremities should be amputated. If area is extensive use skin grafts early. Resulting contractures require plastic surgery. Avoid kidney irritation by prompt local treatment, together with diuretics. Potas-ium citrate, twenty grains, and spirits of nitrous ether, twenty minims. If burnt area is near joints, use splints to overcome contractures.

Complications, as meningitis, pneumonia, nephritis, and duodenal ulcer, require their appropriate treatment.

During convalescence give iron, plenty of food, fresh air and exercise.

(To be continued.)

Therapeutic Notes.

Prophylactic and Curative Treatment of Intestinal—Milian, in Paris Medical, April 10, 1913, states that the prophylaxis of this affection consists in keeping the skinfolds scrupulously clean and in the local use of alcohol or iodized or camphorated alcohol.

Where the affection is established the measures suitable are those which will kill the parasitic
streptococcus and render the local conditions less favorable to its pullulation. Free use of soap and water is useful to remove the superficial coccus bearing skin layers, but the region must be very carefully dried. A better plan is to cleanse the area with alcohol or camphorated alcohol, and this should be done three times daily. Once in each day an application of diluted tincture of iodine may be substituted for the alcohol washing:

R Tinctura iodi, .................. 5₈₈ (a c. c.);
Alcoholis, .................. 5Ⅱ (8 c. c.).

Misce.

Only in rebellious cases may the pure tincture be applied, and this should be done only once, or at least, only after an interval of four or five days.

After each alcohol ablation, the area involved should be dusted over generously with sterile talcum powder. Wads of cotton may also be used to keep the adjacent surfaces apart.

The above mentioned simple measures are generally sufficient. In very obstinate cases, however, the area may be painted every four days, by means of absorbent cotton, with a solution of silver nitrate:

R Argenti nitriti, .................. 5₈₈ (2 grammes);
Acque destillati, .................. 5₉₈ (40 grammes).

Solve.

The surface should be carefully freed of all fatty material before applying the silver solution. Afterward, a rod of metallic zinc should be passed over the skin. The silver salt becomes reduced thereby, and the silver is precipitated on the affected area, which becomes black. Finally either talcum powder or the following zinc paste is applied:

R Zinci oxidi, ..............
Petrolati, ..............
Adips lami hydrosi, ..............
M. fr. unguentum.

This preparation is very advantageous in isolating the diseased surfaces, yet permits of evaporation from the skin, by virtue of its porous consistence. The silver nitrate and zinc lead to the action of nascent nitric acid on the tissues, and give rise to some pain. But the results are excellent.

No special diet is necessary in the treatment of intertrigo.

Treatment of Chorea.—J. Comby, in Bulletins et mémoires de la Société médicale des hôpitaux de Paris, February 7, 1913, points out that by giving arsenic in large doses for a short period only, therapeutic results are obtained with much less danger of toxic phenomena than when small doses are given for weeks and months. He advises the following measures for chorea:

1. Rest in bed for two weeks, with relative isolation; no playing with other children or mental work.
2. Milk diet, consisting of 200 grammes (six ounces) of milk every two hours. This facilitates the taking of the arsenic. Vegetable foods should be added after the ninth day.
3. Arsenic in the form of Boudin's solution (one to 1,000 arsenic trioxide in water), given in a flavored gummy mixture, of which one tablespoonful is given every two hours, with the milk. Each day a new mixture is made, the successive preparations containing, respectively, 5, 10, 15, 20, 25, 20, 15, 10, and 5 grammes of the Boudin solution in admixture with 120 grammes of the gummy menstruum. The entire arsenical treatment thus takes up only nine days. In children, five to seven years old, the amounts of Boudin's solution employed are reduced from the scale mentioned, ranging from three to fifteen grammes, while in those under five years the amounts are from two to ten grammes.

If vomiting should appear, the arsenic is left off for one half to one day. If it still recurs after this, arsenical treatment should be abandoned. In this way all possibility of serious toxic effects is eliminated. Among over 300 cases treated with arsenic in the last thirty years, but one case of arsenical polyneuritis—with subsequent recovery—occurred: in this patient, a little girl, seven years old, treated nearly twenty years ago, the dose of Boudin's solution had been carried up to thirty-five grammes a day. As a rule, the remedy is well borne and the effects are promptly manifested. The choreic movements stop in a week, and in two weeks the chorea is cured. Among 175 children treated since 1906, 135 were given the arsenic, the remaining forty being milder cases. The average stay in the hospital of the arsenic treated cases was twenty-eight days.

Albuninuria and very hot weather contraindicate the arsenical treatment. In hot weather the copious perspiration and diminished urinary flow decrease the tolerance for arsenic, as well as for antipyrine or any other active drug. In such periods hydrotherapy, especially the cold pack, should be relied on to subdue the nervous excitation.

Treatment of Otorrhea.—G. Laurens, in Nouveaux remèdes, April 24, 1913, is credited with recommending that in simple forms of otorrhea the external auditory canal be filled morning and evening with hydrogen dioxide solution, which should be allowed to remain two minutes, evacuated, then reintroduced two or three times more. The canal should then be carefully dried with cotton on an applicator and the following solution instilled:

R Acidi pierici, .................. gr. xv (1 gramme);
Acque destillatæ, .................. 5Ⅱ (25 grammes).
Fiat solutio.

Treatment of Acute Articular Rheumatism.—Roch, in Revue médicale de la Suisse romande, February, 1913, writes concerning a case of rheumatic fever in which, although sodium salicylate appeared at first to be giving excellent results, the pain, joint enlargements, and fever later returned, the heart rate increased, and the systolic sound became muffled. Ten days' energetic treatment with the salicylate proving completely ineffectual, eight grammes (two drachms) of antipyrine were administered in two days, and the salicylate in daily doses of five grammes (seventy-five grains) resumed immediately after. The fever was thus rapidly overcome and convalescence entered upon. The return to a massive dose of the salicylate after the two days' intermission seemed to the author the essential factor in the benefit obtained. Interrupted administration of the salicylates has already been recommended for obstinate cases, and antipyrine seems especially suitable for use during the intervals.

CLINICAL EUGENICS.

Much is written nowadays concerning the influences of heredity and the many conditions which favor the procreation of defectives. The new science of eugenics, though in its infancy, is asserting its right to perpetuation by opening channels which possess all the attributes of success: a useful purpose and clearly defined lines of research, with many data, biological, medical, and statistical, as working factors. Yet reckless, unwise, and even cruel legislation will soon compromise its future if, while providing for future generations, the present generation is caused unjustly to suffer.

Physicians should not forget that modern resources increasingly render possible what might be termed “clinical eugenics” in the sense that many unfortunate victims of parental defects are now amenable, through therapeutic and hygienic resources, to improvement attaining at times a degree well calculated to excite wonder. We have but to recall the transformation witnessed in cretinic idiots under thyroid preparations, followed by grafts of thyroid tissue to compensate for the defective gland, to convince ourselves of the purely organic character of the underlying cause and of the potency of the means to correct it within our reach. That the stigmata of the cretinic idiot lurk behind a fair proportion of our patients is familiar to those who can read what modern thought has taught. Defective development, as obtained in animals through removal of the thyroid apparatus, is as clearly depicted in these cases as are the physical phenomena of fully developed mitral disease to the trained diagnostician. We may witness twenty symptoms or we may recognize but one. The whole gamut of myxedema may at once reveal itself or the early morning occipital pain may alone be present to attract attention to a general condition which the further detection of many apparently minor phenomena will then demonstrate. Not a small proportion of our cases of rheumatism, so called, belong to this type of hypothyroidia—the underly and removable cause of a form of feeblemindedness even now under the ban of the law in several States.

No less prominent is the influence of the adrenals on development. The puppy deprived soon after birth of one of its adrenals, as compared to a normal control from the same litter, is feeble and thin, the muzzle being small and tapering, the hair short and woolly, and the bones slender. Corresponding stigmata and many others may readily be discerned in the hypoadrenic child. The pale, pampered offspring of the rich, as well as the waif in the slums, are on equal terms on this score. The emaciated figure, the pale, pasty, or senile facies, the cold extremities, the muscular weakness, etc., recall few or many of the symptoms of Addison’s disease—the maximum type of adrenal insufficiency. This disease, as every physician knows, includes in its wake vulnerability to infectious diseases—the bane of such sufferers. Here again, we meet disorders, increasingly placed under the ban of the law, that are traceable to an organic cause—one increasingly within the reach of therapeutics.

The ductless glands, owing to their—now established—influence on development, physical and mental, and many other facts which the laboratory and the clinic are steadily accumulating, are increasingly asserting themselves as organs which bear the brunt of certain hereditary influences and through which at least some stigmata affecting the organism at large may be counteracted. And this is but one of the many directions in which we could at least try to defeat morbid hereditary influences.

Clinical eugenics, thus understood, will be an extension of eugenics proper which aims to improve the physical and moral qualities of future generations; it will strive to rid of stigmata, not only in those who have inherited them, but also in their offspring. But it will do what present efforts do not include, namely, providing for those whose unfortunate fate it was to inherit paternal defects before preventive measures had ever been devised.
THE ETIOLOGY AND TREATMENT OF BLACKWATER FEVER.

No satisfactory degree of unanimity has hitherto been reached as to the circumstances favoring the development of blackwater or hemoglobinuric fever in malaria. Some have considered the condition due to pernicious malarial infection in cases where quinine brought relief; others, directly to quinine intoxication. Newell and Chalmers agree that there is both a quinine hemoglobinuria and a malarial hemoglobinuria. In the treatment of blackwater fever the practice generally followed has been that of Bastianelli, who gives quinine provided malarial parasites are present in the peripheral circulation. In an article recently published by Lovelace (Archives of Internal Medicine, June, 1913), based on 514 cases of blackwater fever treated by American physicians in the hospital of the Madeira-Mamore Railway, Brazil, considerable light is thrown on some of the obscure points relative to this affection. In the first place, the direct causal relation of malarial infection to it was rendered obvious, no case of blackwater fever being observed in which there was not a history of fever, apparently malarial, a few days or weeks previously; almost invariably there had been numerous attacks extending over many months. Again, it was noted that, in contrast to previous observations, patients harboring the tertian parasite were nearly twice as liable to hemoglobinuria as those with the estivo-autumnal; whence the author concludes that the condition is not due to any particular species of malarial parasite. Another significant fact was that quinine, in large or small doses, had invariably been taken a few hours before the onset of hemoglobinuria; recurrences of the latter, after the patient had become able to be up and about, likewise followed the use of quinine.

With regard to the treatment of the condition, Lovelace warns against giving quinine during the period of hemoglobinuria, and for several days thereafter. The paroxysm itself has the effect of a drastic, but only temporarily acting, therapeutic agent, decimating the malarial parasites in the blood much as does salvarsan the spirochetes of syphilis in the lesions of that disease. The chief indications in the treatment are to supply water abundantly and to nurse carefully. Saline solution, given continuously as the “Murphy drip,” at the rate of seventy-five drops to the minute, is usually necessary. Vomiting is to be treated by starvation and a mustard plaster; if these fail, by the administration of a glass of water containing two or three drachms of sodium bicarbonate, and, ultimately, by morphine. Measures sustaining the blood pressure are urgently indicated. Digitalis and caffeine, both given intramuscularly in full doses, are of decided value. Every particle of the patient’s strength must be saved. Neither the presence of parasites in the blood nor chills and fever indicate quinine until the urine has been clear for several days. Lovelace then begins cautiously with one grain doses of quinine tannate, three times a day, and gradually works up to twenty or thirty grains of the hydrochloride daily.

Although quinine precipitates blackwater fever, the systematic and adequate quinine prophylaxis of malaria constitutes also the prophylaxis of hemoglobinuria. Lovelace observed that among laborers who took regularly ten grains of quinine daily blackwater fever was very rare; in the few cases in which it did occur there had been numerous mild attacks of malaria, in spite of the quinine. Among those, on the other hand, who neglected to take their quinine until they became ill, hemoglobinuria was common.

VENEREAL DISEASES IN CANADA.

How best to cope with venereal diseases, to eradicate them if possible, is the problem which, at last, is being openly recognized as the one which most greatly needs solution. By the medical profession the question of averting, of abolishing, or at least of minimizing, the menace of syphilis and gonorrhea has been regarded always as paramount. But in English speaking countries, up to the past few years, the medical profession, although profoundly cognizant of the gravity of the situation, has feared to face the matter squarely. That is to say, the public has been so prudish with regard to the subject that mention of it has been virtually tabooed by the lay press. Thus, in this country and in Great Britain and its dominions, the people at large are to a great extent ignorant of the awful effects which may and do follow the contraction of venereal disease, and especially of syphilis. However, recently a decided change has come over the attitude of the man in the street in this respect. Intelligent men and women of the English speaking race are becoming alive to the dangers of venereal diseases and to the foolishness of a laissez aller policy. For this altered outlook in the country perhaps the chief credit is due to the late Dr. Prince A. Morrow, who was insistent and persistent that measures should be taken at once to abate the evils that go in the wake of syphilis and gonorrhea, and who urged continually that the main means of achieving this object was to educate the community at large.

At the opening meeting of the first public health section, held under the auspices of the Canadian
Medical Association, in London, Ontario, on June 24, 1913, over which Dr. Helen MacMurchy presided, the discussion on venereal diseases was made a special feature. During this symposium on venereal diseases as a practical public health problem papers were read by Dr. H. W. Hill, of London, and Dr. F. A. Clarkson, of Toronto. Doctor Hill drew a comparison between syphilis and typhoid fever, and concluded by contending that syphilis should be dealt with in the same arbitrary manner as typhoid fever had been dealt with. Typhoid had been completely robbed of its sting by the stringent methods put into force, and he saw reason to believe that syphilis might be controlled if measures intelligently thought out and rigidly enforced were put into practice. Doctor Clarkson’s paper pointed out the great dangers of existing conditions, and proposed a resolution that the Public Health Section of the Canadian Medical Association should take action (which he specified) calculated to ameliorate such conditions. In the discussion which followed the reading of these papers several speakers took part, and while somewhat diverse views were expressed, the consensus was in the direction of employing educative measures. Professor George Adami, of Montreal, for instance, was strongly in favor of instructing the public as to venereal disease, and he referred to a popular lecture he gave on the subject at the meeting of the Canadian Medical Association at Edmonton last year. Professor Adami thought that, as a first step, statistics should be procured bearing on the prevalence of venereal disease, and suggested that the medical profession, in waging a campaign of education against such diseases, should lay particular stress on the health point of view and ignore as much as possible the moral aspect. Professor Halpenny, of Winnipeg, agreed that the moral side of the question should not be dwelt upon, and thought it might be wise to request hospitals and jails to report separately on venereal diseases.

Dr. R. E. Wodehouse, of Port Arthur, gave it as his opinion that sexual hygiene should be taught by medical men to parents, this knowledge to be passed on to children, or even that medical men should instruct boys and girls directly in the principles of sexual hygiene.

The conditions in Canada as regards venereal diseases are similar to those which prevail in this country, and it is encouraging to note that in Canada, as here, the medical profession and a small proportion of the general public are arousing themselves to fight the hydraheaded monster. Progress must naturally be slow, for the whole matter bristles with difficulties. The public generally is still apathetic, and it will take a considerable amount of education to bring the mass of the population to a sense of the danger to the race and the individual presented by unchecked venereal disease. The hopeful feature of the situation is that some of the most intelligent of the community now recognize the true state of affairs, and that it is likely that they will act as the apostles of reform in this direction.

—

RADIUM TREATMENT OF MYELOGENOUS LEUCEMIA.

According to the Presse médicale for June 18, 1913, radium treatment has been shown by Renon, Degrais, and Dreyfus to exert an immediate very powerful action on myelogenous leucemia when applied over the enlarged spleen for twenty-four hours in relatively large amounts. After three or four applications of from thirty to thirty-three centigrammes of radium sulphate, the spleen was found by these observers to return to its normal size and the total and differential leucocytic counts to their physiological level, while all the general symptoms disappeared. These effects were noted in five cases, all of which had previously been subjected to the Röntgen rays. In two patients recurrence took place two and sixteen months, respectively, after cessation of the treatment, and its resumption failed to yield the results previously obtained, possibly owing to insufficient dosage. The authors call attention to this mode of treatment, however, because it may prove useful in dealing with patients that cannot be removed to the office of the röntgenologist, and is capable of arresting for a considerable time the progress of the disease. In view of the possibility of a difference between the physiological effects of radium and those of the x ray, the authors suggest that these two agents be tried in alternation or association.

—

THE WASSERMANN REACTION.

Although this reaction has received much attention and is generally recognized as being of the greatest value, there are many who do not understand its theory. They believe it to be a very specific reaction, one that takes place only when syphilitic tissues are used. Yet, strange as it may seem, the presence or absence of syphilitic changes in the material used as antigen is of no importance: all that is needed is the presence of lipoids, for it has been found that in syphilis, and in a few other diseases, there are formed certain antibodies that have no affinity for any special cell, but which have the power of reacting with substances belonging to the class of lipoids. These antibodies are not
formed by the Treponema pallidium when grown in cultures, but are present in the blood and tissues of the infected individual as secondary products. The treponema is of little value as an antigen, the Wassermann reaction not being satisfactory when an extract of the culture is used. Consequently, it must be remembered that we are not dealing with a true specific immune reaction, but with one that is more of a group type. Therefore, those other conditions that may give rise to the formation of these lipid combining substances must be ruled out. Fortunately, they are few in this part of the world, and a positive Wassermann test will generally be a true indication of syphilis, although the combination is that of a nonspecific antibody with complement and lipid.

Obituary.

JOHN S. WARREN, M. D.,
of New York.

Dr. John S. Warren died at Atlantic City, N. J., on Friday, July 18th. Born in Middletown, N. H., on July 4th, 1841, he received his education at Dartmouth College, and at the Jefferson Medical College in Philadelphia, from which he was graduated as M. D. in 1866. While still at college, he saw active service during a portion of the civil war, being stationed at Paducah, Ky. From 1860 to 1898 he practised in New York city, where he took active part in the medical societies. In 1908, he retired from practice.

GREGORY DOYLE, M. D.,
of Syracuse, N. Y.

Dr. Gregory Doyle died at Syracuse, N. Y., on Wednesday, July 23d. Born in Ireland on March 28, 1840, he came to America the following year, and was a student at the Niagara University from 1857 to 1860 (LL. D., 1868); and at the University Medical College (New York University) from which he was graduated as M. D. in 1865. After graduation he settled in Syracuse, where he practised until his death. Doctor Doyle was Health Commissioner of Syracuse from 1899 to 1904, president of the United States Pension Board at Syracuse from 1885 to 1889, and Surgeon and Major, N. G. S. N. Y., from 1872 to 1890. He wrote extensively on medical subjects and was the author of Incidents of European Travel (1910). Doctor Doyle was one of the foremost surgeons of Syracuse. He died after a long continued illness, aged seventy-three years.

JOSEPH KIRBY CORSON.
of Plymouth Meeting, Pa.

Dr. Joseph Kirby Corson died at Plymouth Meeting, Pa., on Thursday, July 24th. Born at Plymouth Meeting in 1837, he entered the service of the medical corps of the Sixth Pennsylvania Re-

serves early in 1861, and at the close of the Civil War was transferred to the regular army, receiving a major's commission, and being retired, at his own request, in 1897. He received a gold medal from Congress for heroic work at the battle of Bristoe Station, Va., where he, with other members of the corps, distinguished himself by carrying off wounded Union soldiers under artillery fire from the enemy. Most of the thirty years of service were spent in Indian campaigns and in army posts in Wyoming, Idaho, and Arizona. He was the son of Dr. Hiram Corson, deceased, and is survived by his widow and one son, Dr. Edward F. Corson.

Hospital for Pellagra Patients.—It has been reported that the United States Public Health Service will establish a receiving station in Spartansburg, N. C., for pellagra patients.

Examination for License as Assistant Director of Educational Hygiene.—The Department of Education of New York city has sent out a notice containing the conditions of the examination which will be found in our Miscellany column.

Salvation Army Free Dispensary.—A free surgical dispensary is being installed by the Salvation Army at 2005 East State Street, Columbus, Ohio. Emphasis will be laid on the treatment of diseases of the eye, ear, nose, and throat, but all diseases will be treated. The dispensary will be largely for the benefit of children of the 1,300 families on the visiting list of the Salvation Army. Children sent from the juvenile court also will be given care. It is planned to have the dispensary ready for operation by the middle of August. Among the physicians who will donate a part of their time to the work are Dr. G. G. Sanor, Dr. A. C. Miller, Dr. Robert Leach, Dr. Caspar H. Benson, and Dr. J. W. Ranmer.

Medical Society of the Missouri Valley.—The twenty-sixth annual meeting of this society will be held in Omaha, Neb., September 18-19, 1913, under the presidency of Dr. H. B. Jennings, of Council Bluffs, Iowa. The program in medicine will be given by Dr. Alfred C. Crofton, and the program in surgery by Dr. Charles Mayo. The scientific program will comprise twenty-five papers, including a symposium on pregnancy. The arrangements are in the hands of a committee, of which Dr. W. D. H. Gunnar, and the Omaha-Douglas County Medical Society will be the host. Those desiring to read papers should send titles to the secretary at once, as only twenty-five papers can be entered. Programme will be closed August 1st. Contributions from internists especially welcomed.

Death Rate for New York City for the Week Ending July 12th.—There were 1,270 deaths and a rate of 12.30 in 1,000 of the population reported during the week ending July 5th, as against 1,390 deaths and a rate of 14.02 for the corresponding week of 1912, a decrease of 120 deaths and 1.7% points. If the increase in population be taken into consideration, the decrease is represented by 177 deaths. The most noteworthy fact of the week's mortality was that for the first time in many years no death was attributed to scarlet fever. Measles, diphtheria, croup, and whooping cough showed a slight decrease from the figures of last year; typhoid fever a considerable decrease. Diarrheal diseases under five years of age showed a much decreased mortality, due in part to the more favorable atmospheric conditions prevailing compared with the same week of 1912, which were accountable for the large decrease in the number of deaths from heatstroke. The reduced mortality prevailed at all ages, there having been thirty-nine fewer deaths among the under one-year of age, sixty less between five and sixty-five years, and twenty-eight less at ages over sixty-five years. The death rate from January 1 to July 12, 1913, was 18.48 as against 14.01 in 1,000 during the corresponding period of 1912.
The New York Ophthalmic and Aural Institute.—This Institute, founded by Dr. Herman Knapp in 1869, moved from 44 and 46 East Twelfth Street to its new building at Fifty-seventh Street and Tenth Avenue, on October 1st. The new hospital is a specially constructed seven story building for the treatment of eye diseases.

Typhoid Fever in Sherborn Asylum.—It has been reported from St. Louis that thirty-five cases of typhoid fever have appeared at St. Mary’s Female Orphan Asylum; four deaths from the fever have occurred at the home in the last few days, and the institution has been put under quarantine. The source was traced to a girl who had suffered from typhoid fever and who had been found to have been a typhoid bacillus carrier. There are 250 inmates in the home.

Golden Jubilee of the Milwaukee Hospital.—The Milwaukee Hospital celebrated on August 3d and 4th, its golden jubilee. Founded in 1863, with fifteen patients and a staff of four physicians and a few nurses in a small farm house, its first hospital building was erected in 1884. It burned to the ground, when just completed, and was rebuilt during the next year. Within the last ten years, several extensions have become necessary. Its capacity is seventy-five patients, and it has twenty-five physicians and fifty-two nurses. Since the founding of the hospital, 26,087 patients have been cared for.

Hospital for Criminal Insane at Waupun, Wis.—The new $200,000 hospital for the criminal insane at Waupun, Wis., which has been in process of construction for the past year, will be ready for occupancy about September 1st. At that time it will be ready to care for fifty patients, most of whom will be insane criminals to be transferred from the Northern Hospital at Oshkosh. The institution will care for insane criminals, criminal insane, and vicious insane, and will have quarters to care for fifty the first year and 150 the second year. The structure, which is built of terra cotta brick with Bedford stone trimmings and readymade concrete where needed, is located on seventy-two acres of land just west of the Chicago, Milwaukee & St. Paul tracks, southwest of the city. It is absolutely independent of the State prison in location and has no connection in administration or any other way with the prison. The buildings, which are of fireproof construction, are arranged on the unit plan, the only suggestion of a prison being the barred windows of the inmates’ rooms and the wall in the rear, which will enclose the exercising park. The management of the institution will be much as the one at Matteawan, N. Y.

Money for Hospitals in New York State.—The Board of Supervisors in Cattaraugus County on July 8th appropriated $18,000 to build a county hospital and appointed a committee to acquire a site which had been recommended by an investigating committee previously appointed by the board. The day before the Board of Supervisors of Onondaga County approved plans calling for an expenditure of $154,000 for the building of a tuberculosis hospital in that county. The board also appropriated $37,000 to pay the award of the court and costs in the condemnation proceedings to acquire the Hopper’s Glen site. This is a successful termination of a long fight in the courts for a site which the Board of Supervisors of that county selected three years ago.

On Wednesday, July 20, the Board of Supervisors of Schenectady County appropriated $10,000 for a twenty bed addition to the County Tuberculosis Hospital. The hospital in that county has been in operation three years and has won public approval to such an extent that only one vote was recorded in opposition. The only expressed opposition to the appropriation was from a supervisor who wanted to build a forty bed addition to the hospital. The hospital is now filled and has a waiting list, although eight patients are being cared for in tents. The Board of Supervisors of Saratoga County on Tuesday, July 1st, increased its appropriation for a county tuberculosis hospital from $8,000 to $30,000 and let contracts for the construction of the hospital. The Board of Supervisors of Suffolk County on Tuesday, July 1st, voted to buy a site at Holtsville for the establishment of a tuberculosis hospital. While no appropriation was made for construction, the actual acquisition of the site by the county for this purpose undoubtedly means that the tuberculosis patients in Suffolk County are soon to be provided for.

Precipitation of Uric Acid in the Blood by Means of Uranium Acetate.—A. Oszacki states that the separation of albumin from serum fluid by means of uranium acetate is also of value, clinically, for distinguishing uric acid in the blood. The principal advantage of this method is its simplicity and accuracy, the achievement of which has, up to now, offered the greatest difficulty in determining uric acid in the blood.

Removal of a Plate with Three Teeth from the Esophagus without Opening.—F. Franke says that under narcosis he made a long lateral incision on the side of the throat, close to the esophagus, without incising this. The teeth, which were quite firmly lodged, could not at first be removed; this could not be effected until they had been forced upward, and could be held by a forceps inserted through the mouth, when, by pressure from below, and pulling with the forceps from above, and by
means of several cautious manipulations, they were withdrawn. The patient suffered pain for thirty days after removal. The author advises this method before resorting to esophagotomy.

June 10, 1913.

Character and Treatment of Heatstroke.—A. Hiller presents the following: The heat of our climate (Berlin) does not act directly on body temperature, but on the nervous system, diminishing physical and mental capacity. It also develops neurasthenia and hysteria. Heatstroke, on otherwise healthy people, usually causes them to fall in a faint on the street: face pale, covered with sweat, lips blue, pulse small and rapid, respirations shallow and frequent, temperature not high, and the patient temporarily unconscious. Placing the patient in the shade, relieving the pressure of clothing, and sprinkling the face and chest with cold water, usually restores consciousness, and a drink of freshly made coffee (free from chicory) enables him to walk home. But should heatstroke fell a neuropsychic or psychopathic individual, the author mentions four different types of serious consequences which may result: the exhaustive, asphyxiative, paralytic, and psychopathic. In these the blood is dark red, caked, with the power of coagulation lost, and an acid reaction. By microscopical examination there is found great decrease in red blood corpuscles, a colorless stroma, yellow colored plasma, and quantities of detritus. The clinical aspect presented may be (1) deep coma; (2) periodic cramps; (3) vomiting and diarrhea; (4) high temperature. Treatment consists in exciting the natural excretory channels, the kidneys, skin, and bowels; plenty of sleep and rest; suitable nourishment, with wine. The mental state becomes normal in a few weeks under this treatment, and recovery follows in variable periods of time, though some patients may retain permanent disabilities.

Experience with Noviform.—R. Patek says that noviform is odorless, nonirritating, excisicative, and astrignent, and may be used as a preferable substitute for iodoform.

June 24, 1913.

Sedobrol.—Engelen says that sedobrol is the latest bromide preparation. It is a pleasant tasting remedy, free from sodium chloride. In appearance, odor, and taste, it resembles a concentrated bouillon. It has no ill effect on the mucous membrane of the stomach. The author considers the remedy an important addition in psychotherapy.

Contribution to Anodal Treatment.—A. Schneé explains that in dry and sunny weather the atmosphere contains greater quantities of ions than in damp and cloudy weather. There is a constant excess of either positive or negative ions, these free ions being chiefly derived from radioactive gases emanating from the earth, but also originating in part from the ionization of the air by means of the ultraviolet rays of the sun. During the months from June to October the negative ions of the air are relatively higher than during the months from November to May. Winter fogs cause a decrease in negative ions. Equally noticeable changes are also observed daily. The author quotes Steffins as having considered that atmospheric conditions influence rheumatic, gouty, and nervous conditions in patients. Steffins compared the changes in human health and the varying ion contents of the atmosphere with the fact that the human being needs a certain number of ions, especially the negative, in its immediate environment, as much as it does nourishment, light, warmth, etc. By the artificial administration of negative ions, as in moor and fango applications, radioactive baths, and other such treatments in rheumatism, gout, nervous phenomena, etc., good therapeutic results are attained.

ZENTRALBLATT FÜR CHIRURGIE.

June 7, 1913.

Treatment of Closed Pneumothorax by Aspiration and Overpressure.—W. Greiffenhagen reasoned that if a lung were collapsed from a pneumothorax it could be expanded to its normal position by removing the pressure in the pleura, and at the same time increasing the pressure in the bronchi, and tried out his theory on a patient twenty-seven years old who had previously been operated on for a tumor of the right kidney. Dieulafoy's aspiration needle was introduced in the sixth intercostal space, in the posterior axillary line on the right side, continuous aspiration was made, and at the same time the patient was made to breathe compressed air. The lung began at once to expand and soon filled its normal space. All of this was done under control by the x-rays. Some days later the patient developed a dry pleurisy on the other side, which recovered in about a week. He considers that the operation of combined aspiration and careful inhalation of compressed air, always under control of the x-rays, is indicated: 1, in delayed absorption of a noninfected closed pneumothorax caused by an internal injury, as in pertussis or by the rupture of a small tuberculous focus; 2, in postoperative pneumothorax, the diagnosis of which is made toward the end of the operation, or which could not be avoided, and has not been absorbed; 3, in uninfected hemotherax when the hemorrhage has certainly ceased; 4, after aspiration of serous pleural exudates when the x-ray shows that the lung is not sufficiently distended.

Autoplastic Thread for Use in the Operation of Herniotomy.—J. Golanitzki takes a narrow strip of tissue from fascia or peritoneum and uses it as a suture. He obtained thirty-five such strips from the hernial sacs of twelve patients. After the sac was stretched out he cut from it three or four strips from one and one half to two cm. broad, and from twelve to fifteen cm. long, which could be threaded into needles after they had been twisted a little. The ends of these sutures he secures with catgut, or some other form of ligature. They are about equal in strength to No. 1 silk, or No. 0 catgut, when twisted to form a thread from three quarters to one mm. thick, and are stronger the wider the strip is before twisting.

BEITRÄGE ZUR AUGENHEILKUNDE.

April, 1913.

Injuries of the Eyes of the Japanese during the Russo-Japanese War.—Ch. Oguchi devotes 228 pages to this subject. First he deals with injuries of the eyes in general, gives statistics con-
cerning them in other wars, and discusses the general nature of the wounds of the eye received in battle. In the second portion of the work the injuries of the various parts of the eye, the cornea, iris, etc., are taken in detail, while the third part is devoted to the clinical histories and pathological findings of forty-five cases in which eyes were enucleated on account of injuries.

May, 1913.

Clinical Studies of Occlusion of the Central Artery of the Retina.—Paul Kober gives first the clinical histories of sixty cases of this nature, and then discusses the clinical conditions found and the course of the disease, beginning with the prodromal symptoms, then the onset of the permanent blind-ness or visual disturbance, the ophthalmoscopic findings, the visual field, the treatment, the course and prognosis. Then follows a comparison of the symptoms that favor embolism with those that favor thrombosis, together with a consideration of cases that seem to favor neither. The general diseases found in his sixty cases were: Heart disease in eleven, 18.33 per cent.; local arteriosclerosis of the retina in eleven, 18.33 per cent.; general arteriosclerosis in fourteen, 23.35 per cent.; cerebral arteriosclerosis (apoplexies) in three, 5 per cent.; nephritis in two, 3.33 per cent.; no general disease in seventeen, 28.33 per cent.; no observations made in two, 3.33 per cent.

ZEITSCHRIFT FÜR AUGENHEILKUNDE.

June, 1913.

Etiology of Phlyctenular Inflammation of the Eyes.—Z. Belenky-Raskin reports the investigation of 100 cases of phlyctenular eye disease with the following results: The cutaneous tuberculosis reaction was positive in ninety-two per cent. of these cases; among the children under five years the proportion was somewhat smaller, eighty-five per cent. The cases in which the reaction was negative do not justify the assumption that the phlyctenular inflammation of the eye finds its foundation in some other disease than tuberculosis, for even some of the negative cases presented positive clinical signs of tuberculosis. Indicanuria is not present with special frequency, so there is no ground for ascribing phlyctenular disease to an auto-intestinal intoxication. The fundamental tuberculosis demands attention in every case, in addition to the usual local treatment of the lesion.

Failures of Magnet Extraction when the Findings of the Sideroscope are Positive.—Max Dalner gives as the causes of failure of the magnet to extract a foreign body, the presence of which is positively detected by the sideroscope, 1. A particle of iron that is outside of the eyeball; it may have pierced the coats of the eyeball twice and be lying in the orbital tissues, or it may be caught in the skin of the brow, lid, or cheek. 2. In very rare cases a piece of iron sticks fast in the walls of the globe or the ciliary body. Sometimes it is encapsulated in an exudate or an organized hemorrhage, but this is the case only when it has been in situ for a long time. 3. The magnetic properties of the foreign body are too slight in proportion to its size.

June 15, 1913.

Pneumothorax Occurring in the Course of Tuberculous Empyema.—Bouchut and Gravier report three cases illustrating the fact that a "cold" pleural abscess may become complicated with pneumothorax. Such a pneumothorax remains latent until paracentesis permits the air, previously confined by fluid, to spread more easily through the pleural cavity, when auscultation reveals its presence. The air enters, not because of evacuation of the pleural contents through the bronchi, but as a result of caseation and fistulization of a subpleural tubercle. This variety of pneumothorax, according to the authors' observations, does not result in inoculation of the pleura with fresh micro-organisms, and, different from the ordinary tuberculous pyopneumothorax, does not aggravate the empyema and render the prognosis worse.

June 22, 1913.

Processes of Disintegration of Nervous Tissues and the Role of the Leucocytes.—E. Malespina discusses the fate of the myelin in foci of myelitis, encephalitis, secondary degeneration of nerves, trunks, etc. While it is well known that the myelin breaks up into rounded bodies, which are taken up by macrophages (either leucocytes or fixed tissue cells) in the form of large granules, the ultimate destination of these macrophages or "granular bodies" is unknown. Malespina concludes from his researches that while most of these bodies are discharged into the lymphatics, some directly reenter the blood, with the contained granules.

PRESSE MÉDICALE.

June 28, 1913.

Hepatoptosis and the X Rays.—M. Letulle states that, as has been revealed through x ray observations, so called "hepatoptosis" is merely a congenital condition. The digestive tract plays no active part in the production of liver deformity, but Letulle reports two cases, illustrating the fact that there may exist a simultaneous malformation of the liver, and the beginning of the large intestines, whereby the latter becomes abnormally movable, and may slip upward behind and even above the liver, in a recess provided for it on the posterior aspect of this organ. The term hepatoptosis is in reality inapplicable, as there has been no descent of the liver.

Permanent Congenital Cyanosis.—G. Heuyer reports three cases of cardiac malformation, all of which were found at autopsy to present the following four abnormalities: Narrowing of the pulmonary artery; interventricular communication; displacement of the aorta to the right; hypertrophy of the right ventricle. This combination constitutes the commonest anatomical condition underlying permanent congenital cyanosis. The author discusses the various theories advanced in explanation of these cases, and concludes in favor of the theory of endocarditis during fetal life.

SEMAINE MÉDICALE.

July 2, 1913.

Hemolytic Splenomegaly and the Role of the Spleen in Hemolysis.—Guido Banti reports a severe case of hemolytic anemia with splenic en-
largement, and an aplastic or anhemopoietic condition of the bone marrow in which splenectomy clearly saved the patient’s life and led to ultimate complete recovery. The interest of the case lay in that it was the first aplastic one in which splenectomy had been performed, all others having been associated with an abnormally active bone marrow, which tended to compensate for the hemolysis. In Banti’s case the operation was followed by an evident reawakening of the hemopoietic function, and this fact showed all the more plainly the value of the operation. The author then describes elaborate experiments which lead him to conclude that, in vivo, hemolytic agents fall into two classes: (1) Those which, like distilled water, act directly and almost or quite exclusively upon the red cells, without active cooperation on the part of the organism; and (2) those which not only act directly on the red cells, but also possess the power to excite in the hemolytic organs—the spleen, and in less degree, the liver, lymphatic glands, and bone marrow—an excess hemolytic function. To the latter class belong the sera, toluylenediamine, phenylhydrazine, etc. Four factors contribute to the formation of hemolytic splenomegaly: (1) An agent causing hemolysis, of unknown nature and situation, and producing toxins which excite the spleen to excessive hemolytic activity; (2) hemolytic hyperactivity of the spleen, due to cytohemolysis, and manifested in enlargement of this organ; (3) an anemia, and (4) icterus, both the result of the excessive hemolysis. Thus, in hemolytic splenomegaly, and in other conditions which the author includes in the “splenohemolytic” group, such as acquired chronic hemolytic icterus, and congenital icterus, splenectomy might prove beneficial in that, even though the hemolysis engendering agents should persist, the chief organ (spleen), through which they did harm, would be eliminated.

**REVUE DE CHIRURGIE.**

*June, 1913.*

**False Spina Bifida.**—E. Estor and E. Etienne point out that there may occur, posterior to the spinal column, congenital tumors containing nerve tissue and enclosed in a sac with walls of varying thickness. A distinction must be made, both pathologically and clinically, between these tumors and spina bifida. They may be accounted for either by defective embryonic development or by the presence of a second, abortive embryo; in the first instance, the point of origin of the tumor would be either in residual portions of the neural ridge, or in some glandular *Anlage*, either normal or adventitious. The authors propose to call these tumors medullosomas, or medulloembryomas. In their clinical differentiation from spina bifida, the absence of nervous disturbances, and of spinal deviation, as well as the totally different external appearance, are important features. The treatment consists of operative ablation, which in the two cases the authors refer to—both with the tumors in the cervical region—gave excellent results. Care should be taken, however, to ligate the pedicle, to prevent loss of cerebrospinal fluid in case the sac or interior of the tumor should happen to communicate with the meningeal space.

**Sarcomas of the Tendon Sheaths.**—J. P. Tournez collected ninety-three cases of tendon sheath sarcoma in surgical literature, and includes brief accounts of each in his article. The tumor was on the upper extremity in sixty-six cases (forty-eight times on the fingers), and in only twenty-seven cases on the lower limb, usually in the plantar or malleolar regions. The growth was on the right side of the body in sixty-six cases, and its appearance had been preceded by traumatism in fifteen. After discussing the pathology, clinical features, and diagnosis of these tumors, Tournez refers to the fact that the prognosis should always be guarded, for while the growth of the neoplasms is slow, and metastasis tardy, the ultimate course of the disease resembles that of cancer. Early wide excision, with conservation of the tendons, may yield a permanent cure, especially where histological examination of the tumor shows a marked preponderance of multinuclear cells. If infiltration of the sheaths and tendons is such, however, that prolonged, careful dissection brings about only incomplete removal, or if the tumor is of the round cell type, secondary amputation of the limb will be required. Recurrence also imperatively indicates operation, though, as a matter of fact, recurrence should not be awaited before amputating in the histologically—more malignant forms.

**Formation of an Artificial Vagina.**—E. Quéné and A. Schwartz discuss the operative technic of forming a vagina from a loop of intestine in cases where the former canal is congenitally lacking. They prefer the Mori modification of Baldwin’s method, in which one extremity of the excluded loop of ileum is sutured to the perineum, to the original Baldwin technic, in which the loop is drawn down at its centre, and opened there, a double vagina resulting. In some cases, however, suture of an extremity of the loop would involve excessive tension on the mesentery, with its vessels; where this is the case, the authors have found that opening and implanting the loop at a point only fifteen or twenty millimetres from its extremity will avoid both undue tension and the necessity of producing a double vagina. The ends of the ileal loop used should both be closed by sutures as soon as the loop has been cut away from the remainder of the intestine, and the lower end opened only at the end of the operation. The authors report a case of their own, and also give histories of the thirteen other cases previously operated by various surgeons, in all of which the results had been good.

**REVUE DE MÉDECINE.**

*June, 1913.*

**Pathogenesis of Opsiuria.**—L. A. Amblard refers in the term “opsiuria” to a delay in the elimination by the kidneys of ingested fluid, as was first brought out by Gilbert and Lereboullet. Whereas in the normal subject the ingestion of 600 grammes of water in four divided doses on an empty stomach in the morning is followed by urination within the first few hours of a larger amount than that ingested, under abnormal conditions, including cases of biliary cirrhosis with splenic enlargement, the period of maximal output may be delayed for a number of hours and the increased elimination even take place during the following night. Amblard has found that in some patients the recumbent posture
removes entirely the tendency to delayed elimination, while in others the period of elimination only occurs during the second half of the night, without regard to the time of day at which the fluid was ingested, or to recumbency or exercise after such ingestion. In still others, moderate exercise in the afternoon, or even mental preoccupation, will cause a drop in the ordinary output of urine on the succeeding morning. The author reviews critically the theories advanced to account for “opsiuria”—delayed absorption, general circulatory disturbance, altered renal circulation, and retention of fluid in the tissues—and concludes that the last named is the most frequently applicable, though in some cases delayed absorption manifestly occurs, owing to resistance set up in the liver. Definite information concerning renal efficiency cannot be obtained from the presence or absence of opsiuria.

**Variations of Cholesterin in the Blood of Hepatic Patients.**—Biscos and Rouzaud measured repeatedly the content of cholesterin in the blood of a large number of patients with hepatic disorder under treatment at Vichy. Those with cholelithiasis and cholecystitis showed an abnormally high proportion of cholesterin, which, especially in the gallstone cases, was usually more or less markedly diminished after the Vichy “cure,” though in a few instances it was increased, owing to too vigorous treatment. In the patients with hepatic disorders other than the above, the cholesterin was either but slightly in excess to begin with, or, if high, was uninfluenced by the treatment.

**REVUE Médicale de la Suisse Romande.**

Intradermal Tuberculin Test in Pediatric Practice.—L. Jeanneret asserts, after experience with the Mantoux intradermal tuberculin reaction in 1,012 cases, in which altogether over 5,000 tests were made, that this reaction is of great value in the diagnosis of tuberculous disease in children less than seven years of age. A positive reaction reveals the presence of any tuberculous focus, whether active, torpid, or healed. It may fail, however, in cachetic states, and in the presence of measles, typhoid fever, or influenza. The size of the area of reaction on the skin generally parallels the extent of the tuberculous focus, though the state of activity of the focus, the cutaneous sensiveness of the individual, and the degree of resistance of the organism to the infection are to be thought of also as modifying factors. Series of tests, which can be made without any risk, may be of prognostic value, the reacting area becoming smaller as the condition improves. They also proved of distinct value as a guide in tuberculin treatment, the area enlarging where excessive or too frequently repeated doses of tuberculin were being given, and becoming smaller again as the amounts administered were diminished. The test was carried out every two weeks.

**Treatment of Rheumatic Nephritis.**—G. Turretini reports a case of rheumatic valvular disease, with repeated attacks of visceral rheumatic involvement and of nephritis, in which salicylic medication regularly caused prompt disappearance of albumin and casts. Such treatment would seem to be directly indicated in similar cases, in spite of the fact that salicylic acid is generally considered a renal irritant. In carrying it out one should make sure, however, of the permeability of the kidneys to salicylic acid by adding to the urine a few drops of ferric chloride solution. A history of nephritis previous to the rheumatism necessitates especial caution in the dosage.

**Tuberculous Pneumonia Followed by Recovery.**—Tecon reports the case of a young woman who, after a prolonged period of gradual loss of weight, suddenly developed a pneumonic condition, the subsequent course of which, however, was much less acute than that typical of ordinary pneumonia. The sputum contained tubercle bacilli. The general condition remained fairly satisfactory, the appetite good, and the body weight constant, notwithstanding the fever. After six months’ of illness, recovery took place. In the presence of but few tubercle bacilli in the sputum, and of the other favorable circumstances noted in this case, the prognosis in tuberculous pneumonia should be considered better than in the average cases of this kind met with.

**JOURNAL OF TROPICAL MEDICINE AND HYGIENE.**

**Hepatic Cirrhosis of Malarial Origin.**—Lucius Nicholls classes the malarial liver changes as a monobolobular cirrhosis, the fibrous tissue being increased primarily around the bile capillaries and single lobules of liver tissue. The production of the cirrhosis depends upon the presence of adhesions in the transverse fissure of the liver, thickening of the walls of the gallbladder, and swelling of the neighboring lymphatic glands. The sequence of changes appears to be: (1) The formation of adhesions and enlargement of the lymphatics, pressing upon the bile duct; (2) the swelling of the liver at each attack of malaria; (3) as the adhesions and perihepatitis increase the organ is held as in a vice; (4) thus there is an increased internal pressure, acting against pressure on the bile ducts and in the gallbladder; therefore, fibrous tissue is formed around the bile capillaries as a compensatory act; (5) malarial "toxines" are formed in the liver, and being excreted under unusual pressure along the bile capillaries, add a further irritating factor. The deleterious products which should normally be excreted with the bile are absorbed into the system, and cause the enlargement and profound changes that take place in the spleen.

**Clinical Study of Malarial Fever.**—J. P. Bates applies the term "malarial fever" to all malarias which do not pursue a distinctly tertian or quartan course, whatever variety of parasite be responsible. He describes in detail his observations of the parasites causing irregular fevers, and concludes that there are only two varieties giving rise to such fevers and having gametes of crescentic form, and that both are pigmented in some of their stages of development. These varieties he terms *Plasmodium falciparum subtertianum* and *P. falciparum quotidium*. The so called "nonpigmented parasite" is not a definite variety, but merely a form showing pigment late in its development. Bates next considers fully the symptomatology of
irregular and pernicious malarias. Among 200 cases of malaria of all types in Panama in which the urine was examined, albuminuria was found in forty-two per cent. In the pernicious cases albumin and various casts were observed to be very common. In the rare cases of "algid" and "choleric" pernicious malaria witnessed the symptoms were so strikingly like those of heat exhaustion that the author thinks there must be a coexistence of heat exhaustion and a severe malarial infection to give rise to such manifestations. Although a number of observers have held that there is a variety of dysentery caused directly from malarial infection, Bates agrees with Mannaberg that the former is an accidentally coexistent infection. As regards the differential diagnosis of malarial fever, Bates points out that only the indifferently treated or untreated cases show symptoms of diagnostic value, as mere rigor, fever, and sweating may occur in many other diseases, e.g., tuberculosis, suppurative affections, sepsis, and protracted typhoid. In the poorly treated cases the most marked of the diagnostic symptoms are a peculiar color of the skin, melanemia, jaundice of the sclerae, and splenic enlargement. One feature in the acute malarials that may be of diagnostic value is the bodily distress and pain which so quickly subside with the intermission or remission of temperature, whether these be spontaneous or due to quinine. Aside from these few diagnosis symptoms, the quinine test is regarded by the author as final. A fever continuing for more than five days unchecked by quinine in full dosage is not malarial fever. The author makes it a rule, however, to consider malaria out of the case if the fever is uninterrupted by quinine to the morning of the third day; and, likewise, if the fever is once completely controlled by quinine and a second later rise of temperature occurs without any decrease of dosage or change in the patient’s regimen.

**BOSTON MEDICAL AND SURGICAL JOURNAL.**

*July 10, 1913.*

**The Typhoid Carrier Problem.**—C. L. Overlander doubts the advisability of detaining typhoid carriers in quarantine until some more easy, rapid and accurate method has been devised to determine the presence of the typhoid bacillus in the excreta. Successive negative findings are of doubtful value, and the discharge of such a patient involves a false confidence in his freedom from infected material. He thinks it would be more practical, less arduous, and better conserve the public health to regard each person recovering from typhoid fever as a potential carrier, to carefully instruct such persons concerning this subject and the precautions they should take, and, if possible, forbid them to personally handle public food supplies.

**Report of Eighteen Cases of Separation of the Lower Femoral Epiphysis at the Boston City Hospital.**—Horace Blucy and Fred B. Lund discuss the etiology, pathology, and treatment of these cases, and draw the following conclusions: 1. Owing to danger of subsequent interference with growth, absolute reduction and fixation at the earliest possible moment is of great importance. 2. Early and repeated x-ray examinations are necessary to control the completeness and permanency of the reduction. 3. In simple cases, where immobilization in flexion fails to hold the fragment in correct position from the start, open reduction with the use of a small nail or bone plate is indicated. 4. In compound separation the same means of positive fixation is to be recommended. 5. The foreign body should be removed soon after union has begun, in order to avoid interference with growth. This should be done not later than the third week.

**July 17, 1913.**

**The End Results of Operative Treatment in Thirty-three Cases of Spastic Paralysis.**—Herbert E. Harris found a complete failure in only one case, an idiot. It is generally admitted that when the mentality is deficient and the patient refuses to cooperate by trying to walk, surgical interference with spastic paralysis is likely to be of little use. In the remaining cases subcutaneous tenotomies gave excellent results, whether they were zigzag or not, and in none of the twenty-two cases was there any permanent and undesirable lengthening of the tendo Achillis. Children who have not taken a step have been able to walk as a result of simple division or resection of the adductors and hamstrings. Apparently much can be expected from the Tubby procedure of transfixing the pronator radii teres to work as a supinator. Although the operative procedure may be that properly suited to the individual case, it has been shown that without careful aftertreatment and the long continued afteruse of plaster and apparatus, the various operations are likely to be of little use.

**A Study of 197 Cases of Endocarditis in Children at the Massachusetts General Hospital; with Special Reference to the Treatment of Acute Endocarditis.**—Louis W. Gilbert concludes from this study that acute endocarditis should be considered as acute over a much longer period than has been the custom, and that treatment should be carried out over months, and perhaps years, until all possible signs of acute disease have disappeared, and even then, until adolescence is passed, at least a certain amount of restraint should be exercised.

**Fracture of the Carpal Scaphoid in Childhood and Adolescence.**—William Pearce Coues says that this is one of the rarest of injuries, but that the possibility of its presence should be thought of when children receive injuries of the wrist. Particularly is this true in cases where there is no tenderness over the lower end of the radius and ulna, but pain and tenderness over the dorsum of the hand just distal to the lower end of the radius and in the snuff box. A marked swelling of the dorsum of the hand, stopping abruptly at the radius and ulna, may be of considerable diagnostic importance. A radiograph should always be taken of these injuries, and the scaphoid scanned searchingly for a possible fracture.

**JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.**

*July 19, 1913.*

**The Qualifications of the Surgeon.** by William D. Haggard.—See this JOURNAL for July 5, p. 38.

**One Hundred and Seventeen Cases of Infantile Diarrhea Treated by Intestinal Implantation of**
the Bacillus Lactis Bulgaricus at the Babies' Hospital of the City of New York.—Ralph O. Clock cites most impressive facts which stand out boldly as the result of this method of treatment. There is a gain in weight, in spite of the number of stools, the color of the latter changing rapidly to yellow; and an absence of mucus and blood from the stools at the end of forty-eight hours, accompanied by a rapid decline in the febrile movement. The hygienic surroundings of the patients and the degree of intelligence of the mothers do not influence the results. A starvation diet, accompanied by purgation, which is productive of loss of weight and strength, and which prolongs the course of the disease, can no longer be considered a rational method of treating infantile diarrhea. Infantile diarrhea, even when associated with fever, does not impair the digestive powers to such an extent that the digestion and assimilation of a milk diet are prevented. Corroboration of this fact is found in typhoid fever, where the high caloric diet, in contrast with the starvation diet, has markedly reduced the mortality. Moreover, the cases recorded by the writer prove the value and good judgment of continuing a milk diet in infantile intestinal conditions, as illustrated and emphasized in the diagram of the weights. In severe cases the administration of a large number of the tablets during the first two or three days of the treatment appears to yield the best results. Very young babies have taken as many as forty-two bulgaricus tablets in twenty-four hours without untoward effects. The implantation method of treatment has progressed beyond the experimental stage; the results of its use are beyond question and dispute. It is practical, of clinical and scientific value, and so simple that it should appeal to every practitioner. It is needless to state that a pure culture of the true *Bacillus lactis bulgaricus* must be used if we would secure the best results; otherwise disappointment will follow. It has been found by bacteriologists that the same organism, isolated from different sources, will vary in virulence and in certain other characteristics, and the *Bacillus lactis bulgaricus* is no exception. The bacillus isolated from Bulgarian sour milk has been proved to possess the greatest antagonism to putrefactive bacteria. The culture should show only viable organisms in sufficiently large numbers.

Skin Diseases among Full Blood Indians of Oklahoma, by Everett S. Lain.—See this *Journal* for July 5, p. 43.

Midoperative Diagnosis in Urologic Operations.—G. Kolischer insists that this midoperative diagnosis is of great importance, as evidenced by the fact that the operative procedure must often be readjusted to the conditions discovered. He elucidates this by giving some striking examples. In external urethrotomy, in most cases, the indication for a mere severance of the stricture tissue, or for a more or less extensive resection of the fibrous tissue, cannot be finally decided until the urethra or its remaining portion is exposed to view and to immediate palpation. In Hagner's epididy-}

mtomy, the location and extent of the depleting incisions cannot be decided on until the testicle and its appendages are fully exposed, or whether or not, after puncture of a testicular hydrocele, the tunica testis ought to be removed. It is also evident that in tuberculous disease of the epididymis, the extent of the interference can be determined only after the whole organ is made accessible to sight and manual examination. In suprapubic prostatectomy, the gross differential diagnosis between simple hypertrophy and malignant disease of the gland is only possible when the bladder is opened, and the eventual diagnosis of cancer will influence the decision either to desist from a radical operation or to excise and not to enucleate, if operative measures are at all to be considered. The writer discusses serially the uses of the midoperative diagnosis in many diseases of the bladder, the kidney, and the perineum, and demonstrates beyond a doubt the truth of his assertions as to the value of the midoperative diagnosis in urological operations.

Cutaneous Affections of Childhood, by Alfred Schalek.—See this *Journal* for July 5, p. 43.

The Solubility of Lead Salts in Human Gastric Juice and Its Bearing on the Hygiene of the Lead Industries, by A. J. Carlson and A. Woelfel.—See this *Journal* for July 5, p. 49.

Phenolsulphonephthalein in Estimating the Functional Activity of the Kidneys. A Further Contribution to Its Value.—Charles Goodman refers to a former paper by him, which set forth the advantages of this test. The writer finds that in clinical influenza the small output of phenolsulphonephthalein is out of line with the findings in other general diseases, which show a good output as a rule when there is clinically no evidence of renal involvement. The findings in regard to the value of this test in nephritis, both from a diagnostic and prognostic viewpoint, confirm former conclusions, and the test reveals the degree of functional derangement, and whether the nephritis be acute or chronic. In several of the writer's cases this test revealed a degree of renal insufficiency not evident from the clinical condition of the patient, but confirmed by the fatal outcome of the case. The test has demonstrated renal insufficiency in instances where operation was contemplated, and in which, though chemical and microscopic examinations were negative, subsequent developments confirmed the existence of the renal insufficiency. The writer's findings, in cases of ureteral or renal obstruction, agree with those of Rowntree and Geraghty, in that he found a marked improvement, as indicated by the test, following the removal of the obstruction. In unilateral and bilateral renal disease, the test has revealed the functional capacity of each kidney, and to such a degree as to be of assistance in determining the course of operative procedure. An absence or very small output of the dye from one kidney, with an increased output from the other side, indicates a seriously diseased kidney on the one side, with a compensatory hypertrophy of the other kidney.
The Treatment of Anginal Pains, by Charles L. Greene.—See this Journal for July 5, p. 49.

Potassium Permanganate as a Local Anesthetic to the Genitourinary Mucous Membranes.—Wilfred M. Barton accidentally found (case history given) that the injection of a solution of potassium permanganate into the urethra and bladder caused a transitory but complete desensitization of the mucous membrane of the anterior and posterior urethra, of such a degree and character as to permit the painless passage of sounds. From a series of experiments, the writer has found that anesthesia of the mucous membrane of the urethra so completely and satisfactorily produced by solutions of potassium permanganate in the strength of one to twenty-five hundred, or even in one to five thousand, is incomplete and unsatisfactory when the dilution is raised to one to ten thousand. The minimum dilution producing satisfactory anesthesia is one to five thousand. Solutions in excess of one to two thousand should not be used in the posterior urethra.

MEDICAL RECORD.

July 19, 1913.

Experiences with the Abderhalden Test in the Diagnosis of Pregnancy.—Jacob Gutman and Samuel J. Druskin remind us that the biological pregnancy test of Abderhalden is based upon the fact that at certain periods of gestation detached chorionic cells are found floating in the maternal circulation. This occurs during the development of the placental chorionic villi, their penetration into the maternal tissues, and the formation of inter-villous spaces. The proteins of the above mentioned chorionic cells are different in their composition from those of the mother and foreign to the organism in whose circulation they are floating. The maternal organism reacts against this invasion by a foreign protein with the production of a specific proteolytic ferment. The latter destroys the invader by decomposing it into its primitive or fundamental constituents. These primitive building stones are then utilized for the reconstruction of proteins peculiar to the maternal organism. The fermentes concerned in the disintegration of the more complicated higher nondialyzable albumins of placental tissue into lower, less complicated, dialyzable substances are to be found only in the blood of persons in whom chorionic cells are circulating, i.e., those of pregnant women, and especially in the earlier months of pregnancy. The writers conclude by comparing the results of their experiments with those obtained by a majority of investigators, that the Abderhalden test is perfectly reliable and commendable, but that it is to a certain extent objectionable because somewhat complicated and attended with some difficulties, its performance being therefore necessarily limited to special laboratories. For use by the general practitioner there is need of simplification.

Castration and Operations for Varicocele and Hydrocele without Wounding the Scrotum.—Charles A. Bucklin favors the inguinal incision in castration and in operations for varicocele and hydrocele. These operations can be performed under local anesthesia, induced by the hypodermic injection, into and around the parts, of twenty minims of a ten per cent. solution of novocaine. If a general anesthetic is required the writer prefers pure ether. Where there is a redundant scrotum it can be readily perfected by the removal of a sufficiently large elliptical piece, uniting the edges of the resulting wound by a continuous suture of No. 0 catgut or silk.

Hemorrhoids and Office Practice.—Eric C. Beck claims that operations on hemorrhoids in the office, unless the case is an extreme one, can become the rule rather than the exception. The patient is placed in the Sims position, with the knees well flexed, and is asked to strain. A needle threaded with plain catgut is placed beneath the mucosa into the cellular tissue at the base of the hemorrhoid selected for obliteration, where the bloodvessels enter, and brought out on the other side, thus embracing both the bloodvessels and a small portion of the mucosa. The suture is tied, the loose ends are cut off, and the hemorrhoid is allowed to recede into the rectum. A second hemorrhoid may be likewise operated on at the same sitting. An opium suppository is inserted into the bowel to inhibit peristalsis and to relieve pain. There is no sloughing because only the bloodvessels entering are tied and the blood supply of the mucosa is sufficient without these. There is usually some pain for from twenty-four to forty-eight hours after the bloodvessels have been tied. The writer advises the use of eucaine in weak solution for local anesthesia before operating. The operation is practically the same as that described by J. M. Lynch.

NEW YORK STATE JOURNAL OF MEDICINE.

June 19, 1913.

The Present Status of Nerve Injection.—O. Kiliani reports that in over four hundred cases of facial neuralgia treated by injection in the past few years he has not had a single failure, so far as the relief of the pain was concerned. He uses eighty per cent. alcohol and injects from one to 2.5 c.c. Kiliani regards the treatment as a cure only in so far as it frees the patient entirely of his pain and anxiety. Recurrences are frequent, if not the rule, and in his experience he has seen only about twenty-two per cent. remain free from pain longer than three years. In the rest of the cases recurrences have appeared in from eight months to two and a quarter years. In the cases of recurrence the attacks are much milder and of less frequent occurrence than they were before the first treatment. Where the recurrences follow one another in a given case at short intervals they are very difficult and unsatisfactory to treat. But of nearly five hundred cases thus treated only two have so far come to operation. The injections should be made without any form of narcosis, because the accurate localization of the needle is then possible. The procedure is painful, but the patients are all quite ready to endure a short pain for the prolonged relief to follow. The dangers of the treatment are very slight; one death seems to be attributable to the procedure and destruction of the Gasserian ganglion by faulty injection may lead to corneal ulcer or even loss of the eye. Kiliani has employed the same method with success in the treatment of intractable cases of intercostal neur-
alga and in herpes zoster. In the latter cases the injection has been with from 100 to 170 c. c. of ice cold normal salt solution.

Pituitrin in Obstetrics.—J. K. Quigley reviews the literature and contributes his own observations on twenty-six cases, concluding that: 1. In pituitary extract we have the most powerful stimulant to uterine contraction yet discovered; 2. Its greatest value is in its use in uterine inertia; 3. The ideal time for its administration is in the second stage of labor, but good results follow its earlier use; in such cases it is usually necessary to repeat; 4. No untoward results were seen in his own series, for either mother or child; 5. Its use shortens the third stage; 6. It renders post partum catheterism almost never necessary. The dose is usually 1 c. c., given intramuscularly, repeated in from sixty to ninety minutes if there is no result, or if its effects wane. Elevated blood pressure, myocarditis, nephritis, marked disproportion between the fetus and the pelvic bony canal, or other obstruction, constitute the contraindications to its employment.

The Symptoms and Diagnosis of Involvement of the Heart in Syphilis.—Harlow Brooks and John H. Carroll base their conclusions on the study of two hundred cases. They find that symptoms of cardiac involvement are manifested in a large proportion of cases of syphilis. The symptoms of such involvement of the heart may appear very early in the secondary stage, though they are usually not discovered until the third stage, chiefly because the patient attributes all his symptoms to the general disease, and special visceral signs are neglected. The signs differ from those of idiopathic or simple cardiac cases in a greater tendency toward the involvement of the heart muscle and the coronaries. Precordial pain is probably the most constant symptom and among the earliest. This is often definitely anginal. Cyanosis, dyspnea, and other signs of cardiac incompetence are usually present long before true incompetence is evident. The greater number of cases show combined aortic and mitral lesions in the way of endocardial involvement. Recognition depends primarily on the diagnosis of lupus and the association of a cardiac defect, either of a definite or suppositions nature. The Wassermann reaction, etc., finds its place in the diagnosis of the primary lesions, but the most conclusive and important diagnostic test is the therapeutic one.

Auscultation at the Acromion Process.—Robert Abrahams says that when the apices are perfectly healthy they yield markedly exaggerated normal auscultatory signs when auscultated at the acromions, and the physiological differences between the right and left are exaggerated. In very early infiltration the right shows an appreciably prolonged expiratory sound, a louder spoken voice and increased whispered sound at the acromion; none of which can be heard over the apex on the chest. In first stage tuberculosis this region reveals tubular breathing, bronchophony, and whispered pectoriloquy. Similarly, the left apex yields distinct signs long before the ordinary methods of auscultation would reveal them. The clavicles seem to pick up the sounds and transmit them to the acromion processes with great distinctness.

Thrombosis of the Mesenteric Artery.—Ernest Laplace prefaces his case report with the remark that this, of all the affections of the abdominal cavity, is perhaps the most obscure and most perplexing as to diagnosis and treatment: The etiology is equally obscure, and the condition results in gangrene of the bowel and death. In the majority of the reported instances the condition has been attributed to an endocarditis. The symptoms are usually those of sudden shock, accompanied by abdominal pain, which gives rise to the suspicion of the presence of intestinal obstruction. This latter is promptly ruled out because purgation will always result after thrombosis. In most cases, also, the patient soon begins to improve, there is very little pain, and operation is postponed. In the meantime the intestine is becoming gangrenous, a condition which progresses, so that later an operation is performed only to find a mass of matted and gangrenous gut. If this is removed it is invariably found that the remaining gut undergoes gangrene beyond the limits of the resection, and the end is always in death. One of the most remarkable features of the condition is that the temperature and pulse remain throughout the earlier stages at a point about normal. Laplace's case differed in three very material points from the usual run of such cases. The patient had had two previous attacks of a similar, though very mild, nature, suggesting acute pancreatitis. The last attack, which resulted fatally in spite of operation, presented many symptoms suggestive of acute pancreatitis, and post mortem it was found that such a condition was present. Lastly, there was no suspicion of the existence of a previous endocarditis. Laplace suggests that the extravasation of fluid containing the pancreatic enzymes into the peritoneal cavity during the course of a subacute, or in recurrent attacks of acute, pancreatitis, may lead to the destruction of mesenteric tissue, with the resulting formation of a mesenteric thrombus. This he believes to have been the etiology in his own case, at least.

Acute Membranous Vaginitis in Pregnancy, Due to Enterococcus.—George E. Shoemaker's experience of this condition seems unique, and is confined to two cases seen within a short time of one another. Each of the women was nearing the end of pregnancy when the first symptoms were noticed. The symptoms are local, and consist of the most intense itching and burning, sufficient to prevent any sleep; local soreness, swelling, and a copious discharge of material consisting partly of whitish fluid, and partly of yellowish, cheesy, semisolid masses. Local examination shows redness and swelling of the parts, which are bathed in the white discharge and to which large areas of the semisolid material are found adhering. Removal of this material does not cause abrasion of the underlying mucosa. No ulceration was found. The process involved the entire vaginal tract and extended even into the os of the cervix. Bacteriological examination showed the masses to be made up entirely of the enterococcus, and no epithelial cells or detritus whatever could be detected in them. In the second case the condition was complicated by thrush, which
Proceedings of Societies.

MEETING OF THE AMERICAN THERAPEUTIC SOCIETY.

 Held at Washington, D. C., May 5 and 6, 1913.

President's Address was delivered by Dr. Noble P. Barnes, of Washington, D. C. After treating of recent advances in therapeutics the paper dealt with the medical needs of the day, especially the need of a properly limited materia medica with a rational scientific classification for the use of lecturers, examiners, and students. Many bitter criticisms of so called students of pharmacology, so dowered in the enormity of its proportions, so discouraged in the monotonous memorizing of the meaningless mass, that they failed to collect and retain the wheat, and in due time became drug nihilists, or theorists that some of the drugs were profound remedies. They agreed to treat and practice with the absolutely proved drugs, materia medica, and drug therapy would be placed upon a sound and rational basis. Such a work should include only indispensable drugs and so far as practicable, only those that had been assayed chemically or tested physiologically. The accurate knowledge gained from the study and use of these drugs would soon restrict the multitude of recognized and unrecognized remedies, give better control and better quality to these remedies and enable the student to master everything from solubility to insolubility, everything from methods of administration to variance in action.

The Absurdities and the Commercialism of the Proposals of the Ninth Decennial Revision of the Pharmacopoeia of the United States.—Dr. Oliver T. Osborne, of New Haven, dealt with the drugs which in his opinion should not appear in the coming edition of the pharmacopoeia. Among them were drugs having no therapeutic value. In this conclusion he cited the aspirins, such as lemon peel, condurango, and saffron in the pharmacopoeia with drugs like digitalis; metals and chemicals of no drug value, like aluminum hydrate and uranium nitrate. Drugs not needed or whose effects could better be obtained from other drugs already official (anthesmus, cinchicifuga, yerba santa, gambir, cotton root bark, leptandra, sarsaparilla, snake root, sumblico, prickly ash, etc.); to this class belonged also certain preparations inferior to others, for example, fluid extract of digitalis purpura (there is a better), fluid extract of gentian, fluid extract of cinchona, etc.; mixtures and compounds (in this connection he mentioned such preparations as compound infusion of sena, Basham's mixture, Brown mixture, elixir adjuvants, and pointed out that these could be obtained at a cheaper price); drugs that could not be standardized, like lemon peel. It was also unnecessary to include the parent substance because it was desired to include a derivative. For example, there was no necessity for making the spices official just because it was desired to include their volatile oils.

Dr. Harvey W. Wiley, of Washington, D. C., had had an opportunity to express an opinion as to the substances that should or should not be admitted to the book. He had had no doubt but that some of Doctor Osborne's criticisms were justified, but there was a great difference of opinion upon this point among medical men. If 15,000 prescriptions from physicians were collected and it was found that only one particular ingredient appeared in a considerable number of them, it seemed reasonable to conclude that the ingredient had some therapeutic value. Some of these humble drugs might yet become the head of the corner. He himself had objected to some of the drugs mentioned by Doctor Osborne, and in case of a number of them he had asked a reconsideration, which had been granted. While it was true that some of them could not be adequately standardized it could at least be required that they be put up and made of what was quality.

The Treatment of Diabetes and Pregnancy.—Dr. REYNOLD WEBB WILCOX, of New York, stated that the treatment of a diabetic woman who had become pregnant was as follows: If hydramnos existed, usually in about one third of the instances, or the amount of glucose in the urine was excessive and uninfluenced by treatment, or the loss of flesh or strength was marked and, absolutely, if the fetus was dead, the uterus should be emptied at once. The viability of the child was usually problematic. A diabetic woman should not marry, she should not be allowed to become pregnant. If a pregnant woman had become diabetic, the dangers of labor were increased, not only from impaired vitality and impaired resistance to infection on the part of the mother, but because in severe diabetes a dead and even macerated child might result, or, if the disease was mild, one of average size, which, if the time of labor was not anticipated by operative interference, might endanger the life of both. By succeeding pregnancies a curable might be converted into an incurable diabetes. In the glycosuria of pregnancy each patient must be carefully studied, and the procedure adopted that was justified by the condition of the patient and the persistence of this symptom. When it was shown that pregnancy was somewhat out of his line, he believed that in many cases glycosuria was due to pancreatitis and consequent squeezing of the islands of Langerhans caused by the effects of bacteria escaping from the duodenal core. As soon as this part of the patient was relieved the glycosuria disappeared. The indication was to do away with the bacterial infection if possible.

Dr. J. J. KINYOUN, of Washington, D. C., said that in 200 cases of diabetes he had noted changes in the pancreas with squeezing of the islands of Langerhans in a considerable proportion of the cases. Only in rare instances however did such patients give a history of diabetes.

He was surprised to learn that Dr. Lee had already spoken of uranium nitrate. There was good authority for the statement that it was a poison, particularly to the kidneys, and he did not believe that it could be given without danger. Its therapeutic value was not commensurate with the dangers attending its use.

Doctor Wilcox said that there was no doubt but that uranium nitrate was a poison, but the danger to the kidneys could be obviated through frequent examination of the urine.

The Treatment of Arteriosclerosis.—Dr. Louis F. Bishop, of New York, stated that most cases of arteriosclerosis could be traced to the substances derived from food products. It was the reaction of the individual to the proteins that caused the disease. In almost every case it was the individual to make him more susceptible to damage by protein material. Accordingly he had adopted a system that he called the "few protein diet." All eggs, fish, meats, fowl, and soup were excluded. Cheese was allowed as a furnishing of protein in a safe form, and later chicken was added tentatively. An ounce of castor oil was ordered every forty-eight hours for three doses, then another dose at the end of the week, and later, a dose not less than once a month. Nitroglycerin was given in many cases and the individual to make him more resistant, whether dyspepsia, pain, vertigo, or even edema of the lungs. Exercise and out of door life were essential. For the cure of the arteriosclerosis the underlying causes should be removed, and among these mental stress was important.

Dr. J. MADISON TAYLOR, of Philadelphia, spoke of the importance of the early recognition of the disease. Doctor Bishop had said in a former paper that there were prac-A.

It was worth while for the individual if he had some other form of breakdown, because then the arteriosclerosis might be recognized and treated in its incipient stages. Some of the causes of the disease were particularly of the etiology. Arteriosclerosis was not a general disease of the whole body but primarily a diseased condition of the vessels. At first it did not affect the body as a whole, but was a localized condition. Gradually, however, it might affect one organ or part, and another, the heart, kidneys, nervous system, until the body as a whole.
suffered. Alcohol, overeating, gout, etc., were only predisposing causes in most cases. Laboring men were especially susceptible to arteriosclerosis, but as a rule they were not excessively excitable or overindulgent. But they were hard workers, and work and heredity were important factors in the etiology, whether the individual was a laborer or a financier at his desk. Everyone was furnished with vessels good for a given time under proper conditions. If the use of the arteries was allowed to exceed the natual rate of hardening, which was due to heredity, or to the different factors stated, the disease was decided and the morbid changes were accelerat ed. In general, the use of the arteries should always be within the natural rate; in other words, it would not do to take away meat. General principles of treatment should be broken as conditions necessitated.

Doctor Morris suggested that the response of the blood pressure to certain foods might be utilized as a test for arteriosclerosis in its early stages. Doctor Blackader said that he always hesitated to say that a drug was a specific, and in the same way he hesitated to accept the statement that there was only one cause of arteriosclerosis. Doctor Morris pointed out that the question was one of fundamental importance. Since it had been shown that the disease was due to multiple causes, it was important to determine the relative importance of the several factors. He further said that serious mistakes had been made by trying to adapt one treatment that had been satisfactory in one case to another case. The treatment must be adapted to the particular person. In his own experience with the case of a laborer, for example, it would not do to take away meat. General principles of treatment should be broken as conditions necessitated.

Doctor Osborn emphasized the danger of changing the diet suddenly or radically. The same was true of exercise and other factors ordinarily employed in the treatment. He had obtained good results from the use of potassium iodide.

Doctor Dawes, of Albany, said that the salines or calomel were preferable to castor oil. He had found the constipating aftereffect a decided objection to its use. He agreed with Doctor Fisher as to the span of life of the vessels. The same might be said of the heart. They should be kept in a healthy condition and directed toward undue susceptibility of the tissues—the heart, kidneys, liver, nervous system. He commended the use of castor oil and salines in these cases.

Doctor Osborne emphasized the danger of changing the diet suddenly or radically. The same was true of exercise and other factors ordinarily employed in the treatment. He had obtained good results from the use of potassium iodide.

Doctor Taylor had stated a few years ago that typhoid fever was not infrequently followed by hardening of the arteries. In his own experience he had observed that some hardening was usually observed in tuberculous patients more than in the Atlantic coast in this regard. Cases ascribed to overwork, overeating, etc., were not infrequently the result of syphilis. The disease should be eliminated as an etiological factor before beginning treatment.

Dr. F. M. Potter, of Los Angeles, said that Doctor Taylor had stated a few years ago that typhoid fever was not infrequently followed by hardening of the arteries. In his own experience he had observed that some hardening was usually observed in tuberculous patients more than in the Atlantic coast in this regard. Cases ascribed to overwork, overeating, etc., were not infrequently the result of syphilis. The disease should be eliminated as an etiological factor before beginning treatment.

Doctor Kinyoun said that in the postmortem examination of tuberculous subjects he had found marked arterial changes in forty per cent. of the cases. They must have been due to cases like alcoholism, syphilis, etc., as they anetaduated the tuberculos.

Doctor Bishop said that in his own experience no cause could be assigned in about nine tenths of the cases. In the remaining one tenth the causes were alcohol, lead, syphilis, etc., in which cases the study of the case is largely cited to show that much attention was paid to the advanced cases, and not enough to the incipient cases, although the latter were the most important. Bacterial arteriosclerosis was due to protein poisoning, as suggested by Doctor Morris. Heredity was only a matter of susceptibility after all. He com-

mended Doctor Osborne's definition of iodine as a thyroid stimulant rather than an alternative in these cases. He did not believe in excluding all protein from the diet. The emphasis should be to avoid the particular protein causing the trouble and eliminate it. It was revealed by the special craving of the patient for it when it was withdrawn. As to laborers, many of them had syphilis, and all of them overate. As to salines: A circular issued by the Medical Corps, U. S. A., summarized the effects of antityphoid vaccination up to the close of the year 1912 in the United States Army, both at home and abroad, among the officers and enlisted men. During the last four years approximately 200,000 persons had been immunized, entirely without fatalities, or any untoward results. In the Army none but the healthy was immunized, any illness, of whatever nature, automatically postponing vaccination until after recovery. The immunity, no doubt, diminished gradually, as after smoking, to a point which, however, was above that of the blood pressure when at rest. In the future, it would certainly prove as efficacious in civil life as in the Army, and its extended use would hasten the time when typhoid fever would become a negligible factor in the public health problems.

Current Developments and Problems in Vaccine Therapy. Dr. A. Parker Hitchens, of Glenolden, Pa., suggested that the limitations which at present characterized the treatment of infections by means of vaccines were due, not to the inherent weakness of the vaccine, but to the fact that the classic vaccination had been a pronounced success in the Naval and Military services, in hospitals, schools, institutions, among pleasure seekers and in contractors' camps, especially those located on the coasts of the United States, at San Francisco, New Orleans, and Los Angeles, where the vaccines used were the result of intensive efforts for the last ten years to develop vaccines which would be effective against the prevalent local strains. The most promising field of study for the laboratory man today was the relation of the infecting bacteria to the blood and lymph supply—the possibility of bringing the antibodies formed as a result of the injections into contact with the infecting bacteria. He suggested the use of drugs in infection of the organs to whip up the circulation locally, when the blood was stagnant, as in certain catarhal conditions of the nostrils and throat, to stimulate the circulation, to make the blood flow locally, and when the content of blood in antibodies was greatest, to cause a temporary local congestion with a resulting hypersecretion of mucus and increased outflow of lymph. There were such drugs, and it was the third arm of the weapon, in conjunction with a mere practical knowledge of the pathological changes in infection, that better results in vaccine therapy were to be obtained.
made in the prevention of typhoid by the introduction of antityphoid inoculation in the army. Among the people at large, however, the reaction to the injections interfered with the acceptance of the vaccine and many people would not submit to vaccination, and still more loath to submit to antityphoid inoculation, particularly after they had had one injection. Some way should be found to lessen the unpleasant effects of the first dose.

Doctor Hitchens said that according to Robertson, who had had considerable experience in this line, the vaccines were of value in pneumonia. Not infrequently they failed, however, and it was impossible to predict when failure would occur. He had felt as Doctor Kinoyou did about the use of mixed vaccines until after he had had considerable experience with them, and he had waited before expressing his views until he had become convinced that his conclusions were fully justified by the results. A hodgepodge or shotgun vaccine could not be condemned too severely; but in some cases of mixed injections the indications were clear, and mixed vaccines could be used to advantage.

Doctor Osborne asked Doctor Hitchens whether he had had any experience with antirheumatic vaccination.

Doctor Hitchens replied that he had had no personal experience with it, however. Rheumatism was caused by a specific microbe and that microbe was employed in the treatment he believed that a clinical result could be obtained provided that the antibodies came into contact with the organism in the body. Therein, however, lay the difficulty. In rheumatics who are convalescent, the toxic symptoms appeared the toxines had united chemically with the cells and the problem was to get the antibodies to reach them.

Dioxydiamido-n-benzenc-n-nemethane Sod ium Sulphonate in Syphilis of the Nervous System.—Dr. Edward D. Fisher, of New York, stated that this comparatively new remedy was an important aid in the treatment of syphilis of the nervous system, both in the early manifestations (i. e., cebrosial syphilis) and in the so-called paralytic forms of the disease. With the control examinations of the blood and cerebrospinal fluid it was a rational method of treatment, indicating by the presence or absence of the Wassermann reaction the necessity for continuity or cessation of treatment. With the discovery of the spirochetes in the brain and spinal fluid in tabes and general paralysis, the indication for removing the active agent of syphilis became mandatory. It should be remembered, however, that a single therapeutic chemical change cannot be accomplished beyond preventing the extension of the disease by the still active agent. Too much emphasis, therefore, could not be placed upon the importance of early diagnosis. If employed at the proper time it could be effective in stopping the further progress of syphilitic disease of the nervous system.

Doctor Kinoyou said that during the last two and a half years he had examined a number of tubercular patients for syphilis, and had found a strong positive Wassermann reaction in about thirty per cent of the cases. He was still pursuing the investigation at an institution for boys between twelve and eighteen years of age. So far he had found a positive reaction in twenty-three per cent. of the boys examined.

Doctor Fisher, in closing, said that the effect of the new remedy in neuritis had been rather favorable than otherwise. The Wassermann test was of great value in doubtful cases, like hereditary syphilis, and where there was doubt as to the nature of mental disease, for example, in mental paralysis. The use of a remedy like this, so easy of administration, was liable to be carried to extremes; it sometimes fell into wrong hands and hopes of cure were engendered that were not to be fulfilled; on this account he thought it well to sound a note of warning. In the smaller proportion of cases in which a cure could be expected after a certain point had been reached.

Copper Chemotherapy with Special Reference to the Double Tartrate of Copper Oxide and Sodium.—Dr. Wilfred M. Barton, of Washington, D. C., explained that the experimental part of the investigation was divided into the following headings: 1. Chemical and pharmacological; 2. bacteriological and therapeutic; 3. summary and conclusions. The conclusions were in part as follows: 1. The only compound of copper at present available for intravenous injection was a double salt, such as the double tartrate of copper oxide and sodium; 2, the minimum toxic dose in the rabbit was of the order of 350 milligrams per kilogram, the mixture was given for several days; 3. the chief effects of poisonous doses was a primary stimulation and subsequent paralysis of the peripheral terminations of the affected nerves, involving the bowels and the heart muscle; 4. the solution of the double salt was powerfully antisptic; 5. a quantity corresponding to 0.0053 gramme of CuO prevented the development of an otherwise fatal pneumococcus peritonitis in rabbits, and a like quantity would, without preliminary treatment, be fatal; 6. the injection of the solution of the double salt representing 0.0026 gramme of CuO could be injected intravenously into a rabbit weighing two pounds without any subjective or objective symptoms; 7. the chief objection to the method lay in the fact that the double salt was unstable and the solution must be freshly prepared and specially titrated before being used.

The Application of Some Muscular Tissue Adapted to Physiologic Standardization.—Dr. Ernest H. Muspratt, of Philadelphia, with the collaboration of Paul S. Pittinger, Ph.D., of Philadelphia, presented a paper which was a preliminary report describing experiments for the standardization for fluid extract of ergot by measuring its therapeutic effect. For action. Of the ergot, the toxic and the antispasmodic effects. The muscular tissue of uteri from nonpregnant guineapigs was used. The technic was explained in detail and the results shown upon charts.

The Treatment of Pneumonia with Mercury and Sulphur Therapy.—Dr. Nina Korninskie, of Washington, D. C., remarked that the treatment was applicable in both croupous and catarhhal pneumonia and in patients of all ages. It appeared to end the infectious process in the lungs in a very short time. In patients who responded favorably there was a rapid decline and evacuation of the fever and the expectoration of much mucopurulent sputum. In croupous pneumonia the runy sputum was not abundant and was much less tenacious and glizzy. Treatment should be given for several days, long enough to determine whether the patient reacted favorably. The medicine was administered regularly at two and three hour intervals (two hours by day and three hours by night) for two or three days. When the thirty-second dose did not produce catharsis, half an ounce of caster oil was given to empty the bowels. It was also useful to lessen the discomfort in case the mercury and sulphur combination caused free purgation and colicky pains. When the evening temperature was normal and recovery began, the mixture was continued for six hours intervals. Should no change in the symptoms occur by the end of the third or fourth day, the treatment had failed, and the cause would be found in a complication not previously detected or in an error of diagnosis. The formula of the mercury sulphur combination was as follows:

Hydragrygi bichloridi corrosivi, . . . . . . . . . . gr. ss, 03
Sulphuris precipitati, . . . . . . . . . . . . . . . Si, 8.00
Aque destillatis bulbiculis, . . . . . . . . . . . 15j, 120.00

M. S. Shackle and gave quickly one teaspoonful every two and three hours.

(To be continued.)

Book Reviews.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

In this fourth revised edition of his book for mothers Doctor Fisher has incorporated the latest ideas regarding infant feeding, a subject which is constantly under-
Die vergleichende Methode in der experimentellen Physiologie
Von Wilhelm Trendelenburg, in Innsbruck.

Professor Trendelenburg in his lecture on the comparative method in experimental physiology calls attention to the fact that this method is not superior, and that many important questions as yet unsolved that can be approached only by way of comparing results. Yet the question remains unsettled as to where the site of the irritability of the heart is situated, whether within the muscle or the nerves. In regard to the function of the central nervous system very much information has been obtained by studies on the ape. In fact there is no function of the body that cannot be rendered clearer by such comparative method. This small pamphlet of twenty-four pages contains an interesting review and forecast of the possibilities of such a method.

This is an exceptionally complete reference book on analysis of the urine. It is the use of black of an encyclopaedia. The references are extraordinarily complete and the printing excellent. It has, of course, because of its completeness, a limited field of usefulness. To the physiological chemist, or the clinical pathologist, it should be invaluable.

It is rather a commonplace to praise a new textbook without reserve, and yet it is difficult to find fault with the one in hand. The subjects are well arranged and clearly exposed. The illustrations are unusually good, those illustrating the passage of sounds and catheters under various conditions being far more illustrative than any we have seen. One could dispute the author's views on certain topics. However, the questions he raises are left unsettled. One could find little evidences of carelessness in this as in all other books; such as, for example, figure 248 (representing a renal calculus that looks like a comet), which is upside down. The use of black for titles and type in the paragraph is much too lavish in certain portions of the book, since it spoils the appearance of the page and by emphasizing too much succeeds in emphasizing almost not at all. But these are minor defects in what is after all the best book upon urology that has been published in English in many a day.
thence to Chincoteague and Wachapreague, Va., for the purpose of making the annual physical examination of keepers and surfmen of the Life Saving Service.

Wertenbaker, C. P., Surgeon-G. D., proceeded to possess himself of Cape Charles, Va., not later than the morning of July 24, 1913, for the purpose of making the annual physical examination of keepers and surfmen of the Life Saving Service.

Appointments.

Dr. Daniel S. Baughman, Dr. James B. Laughlin, and Dr. Harry M. Thomzet, commissioned Assistant Surgeons in the Public Health Service.

Board Convened.

Board of medical officers convened to meet at the Marine Hospital, San Francisco, Calif., at 1 o'clock a.m. Monday, July 13, 1913, for the purpose of examining First Lieutenant H. G. Hamlet, United States Revenue Cutter Service, to determine his fitness for promotion. Detail for the board: Surgeon R. M. Woodward, chairman; Passed Assistant Surgeon J. M. Holt, recorder.

United States Army Intelligence:

Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Army for the week ending July 25, 1913:

Card, D. P., Captain. Will make not to exceed eight visits to Fort Wayne, Ind., August 1st to September 1st, 1913, for the purpose of special study in eye refraction, and upon the completion of the duty enjoined will return to his proper station after each visit.

Davis, A. D., Captain. Granted two months' leave of absence for the purpose of assisting in the completion thereof to return to his home by July 30th, and stand relieved from active duty in the Military Reserve Corps.

Dasher, J. A., First Lieutenant Medical Reserve Corps. Is ordered to active duty in the service of the United States for the period from July 21 to 30, 1913. He will proceed on July 21st to Ft. Dupont, Del., and remain on active duty and upon the completion thereof will return to his home by July 30th, and stand relieved from active duty in the Medical Reserve Corps.

Gilchrist, H. L., Major. Will proceed to Montgomery, Ala., and report to the governor of Alabama for the purpose of assisting in the reorganization of the sanitary troops of that State, and upon the completion of this duty will return to his proper station in this city.

Miller, Reuben B., Major. Is relieved from further duty with the Second Division, Texas City, Texas, and will proceed to Fort Wayne, Mich., for the purpose of transferring the public property for which he is accountable. Major Miller will stand relieved from duty at Fort Wayne upon the completion of the transfer and will then repair to Washington and report in person to the commanding, Army Medical School, for assignment to duty as professor of sanitary chemistry, relieving Major Carl R. Darnall of that duty.

Rhoads, Thomas L., Major. Relieved from duty at the Walter Reed Sanitorium, District of Columbia, and will proceed to Winchester, Va., and report in person to the commanding officer, Provisional Cavalry Brigade, for duty, and upon the completion thereof will proceed to Philadelphia, Pa., for duty as attending surgeon in this city.

Shields, J. W., Second Lieutenant. Ordered to duty at Texas City, July 18th, assigned to Fourth Infantry.

The following named medical officers are relieved from duty in the Philippine Department to take effect after August 15, 1913, and will proceed to the United States and upon arrival report by telegraph to the adjutant general of the army for further orders: Lieutenant Colonel Henry A. Shaw, Captain Charles T. King, Captain Mark D. Weed, Captain Wayne H. Crum, Captain W. Cole Davis, First Lieutenant, Medical Reserve Corps, John R. Hereford.

The following named medical officers are relieved from duty in the Philippine Department to take effect after September 15, 1913, and will proceed to the United States and upon arrival report by telegraph to the adjutant general of the army for further orders: Captain Thomas D. Woodson, First Lieutenant, Medical Reserve Corps, Elmer S. Tenny.

The following changes in the stations and duties of officers of the Medical Corps are ordered: Major William H. Rhoads is relieved from duty in Texas, and will proceed to Fort McDowell, Cal., and report in person to the commanding officer of that post for duty.

United States Navy Intelligence:

Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Navy was reported during the week ending July 26, 1913:

Camerer, C. B., Assistant Surgeon. Detached from South Dakota and ordered to temporary duty at Washington, D. C., on July 14th, 1913, to relieve Dr. M. R. McKelvy, and will then proceed to Fort McKinley, Me., and report in person to the commanding officer of that post for duty.

Married.

Mason—Steiner. In Montgomery, Ala., on Tuesday, July 15th, Dr. E. Marvin Mason and Miss Helen Steiner, New York, N. Y.

Died.

Basham. In Little Rock, Ark., on Tuesday, July 8th, Dr. John P. Basham, aged fifty-two years. Blume. In Baker, Ore., on Friday, July 18th, Dr. Samuel Blume, of Riverhead, L. I., aged sixty-eight years.

Cravens. In Chicago, Ill., on Sunday, July 20th, Dr. James F. Cravens, aged seventy-eight years. Doyle. In Syracuse, N. Y., on Wednesday, July 23rd, Dr. Gregory Doyle, aged seventy-three years. Ellis. In Detroit, Mich., on Saturday, July 12th, Dr. Lucien E. Ellis, aged seventy-two years. Evans. In Kansas City, Mo., on Sunday, July 20th, Dr. W. H. Evans, aged seventy-three years.

Fulton. In Kansas City, Mo., on Tuesday, July 15th, Dr. A. L. Fulton, aged seventy years.

Glass. In Johns-town, Pa., on Saturday, July 19th, Dr. Joseph A. Glass, aged fifty-six years.

Kemp. In Baltimore, Md., on Thursday, July 10th, Dr. William A. Kemp, aged sixty-four years.

McCormick. In Leavenworth, Kan., on Thursday, July 17th, Dr. John McCormick, aged eighty-seven years.

McLellan. In Quincy, Mass., on Wednesday, July 23rd, Dr. Roderick McLellan, aged fifty-four years.

Osborne. In Milton, Pa., on Tuesday, July 22nd, Dr. James A. Osborne, aged seventy-three years.

Schaefer. In Canajoharie, N. Y., on Saturday, July 19th, Dr. John Frederick Schaefer, Wright. In Paris, France, on Saturday, July 19th, Dr. A. L. Wright, of Iowa, aged sixty-three years.
DYSENTERY IN THE TROPICS.

By Eugene R. Whitmore, M. D.,
New York,
Major, Medical Corps, U. S. Army.

Dysentery was known in old Egyptian and Indian medicine, and the disease, "atisar," described in old Sanskrit writings, corresponds exactly to the picture of dysentery. Herodotus described as the "war plague" what is probably the epidemic form of today. The later writers of the Greek and Roman periods distinguished "ileteria, dysenteria, and tenesmus," and since that time the disease has been known as dysentery. In the Middle Ages it was frequently called "soldier's plague."

Dysentery is endemic throughout the tropics, and epidemics are extremely common there. However, the disease is by no means confined to the tropics, but is met with in subtropical, temperate, and cold climates. Most of our diseases are cosmopolitan in distribution, but their prevalence varies greatly with the climate. Dysentery is the same disease in the tropics that it is in temperate climates; but it is one of the commonest diseases in the tropics, is one of the leading causes of death there, and is prevalent the year around. The United States Army Board for the Study of Tropical Diseases, in speaking of an epidemic of dysentery in the Philippine Islands, in 1911, says: "Clinically, the most striking feature was the tremendous mortality. Not a convalescent was found or reported, and only one living patient sick more than a week was seen." Castellani and Chalmers' say: "In the tropics dysentery is a more potent factor in the death rate than is malaria, though the latter may cause more illness."

It had long been known that there were two types of dysentery: one which was "endemic," without any great tendency to spread in epidemic form; and another form which had a great tendency to develop extensive epidemics in the tropics and sub-tropics, and also in temperate and cold climates, especially in armies and institutions. In 1875, Lösch' considered that amebae were the cause of dysentery, and Kartulis' and others confirmed this work; but the point remained in dispute, as amebae were not generally found in the epidemics of dysentery, and, on the other hand, amebae were often found in the stools of healthy men. Councilman and Lafleur (1891) made an extensive study of amebic dysentery, which they distinguished from the diphtheritic form of the disease. They considered the Ameba dysenterica to be the cause of amebic dysentery, and suggested that there were several species of ameba, which under certain conditions and in certain localities may inhabit the colon.

In 1898, Shiga found a bacillus as the cause of an epidemic of dysentery in Japan. In 1900, Flexner' found a bacillus in dysentery cases in Manila, and very soon this work was confirmed from all parts of the world; and so dysentery without ameba was explained. In 1903, Schaudinn' showed that there were two species of ameba parasitic in the intestine of man—one, a harmless commensal, frequently found in the intestine of healthy men, and a pathogenic species that causes ulcerative dysentery. Thus was explained the frequent finding of ameba in the intestine of healthy men.

So, leaving aside the rare forms, we have two forms of dysentery—amebic and bacillary—which differ in etiology and morbid anatomy, and require different treatment.

Amebic dysentery, also spoken of as "endemic" or "tropical" dysentery, has its home in the tropics, though it is by no means limited to the tropics, as it occurs in the temperate zone. The disease is endemic in the southern part of the United States, and sporadic cases are met with in the Northern States. The disease is due to a parasitic ameba which was first properly described by Vierck and Hartmann, in 1907:

Morbid anatomy. The lesions in the intestines begin as areas of infiltration in the submucosa of the large intestine—the lower part of the small intestine is rarely involved. The ameba may pass through the mucosa, directly to the submucosa, but there is generally a small area of erosion, with three or four gland ducts involved. The ameba pass down the gland duct, and, by their necrotising action, destroy the cells lining the duct, and so gain entrance to the submucosa. This superficial area of erosion is surrounded by normal mucosa, and, as the main part of the process is in the submucosa, the process has been likened to a boil in the submucosa, and pointing on the surface of the mucosa. The tissue in the in-
volved area becomes necrotic, the mucosa over this area breaks down, and, as the slough separates, an ulcer is left, with its base in the submucosa, or in the muscular coat; or it may extend to the serous coat. As the necrosis is more extensive in the submucosa, the ulcer has undermined edges, and two ulcers may join in the submucosa, leaving a bridge of practically normal mucosa between them. The mucosa between the ulcers is everywhere practically normal (Fig. 1). Great areas of mucosa may become gangrenous; but this is probably due, in part, to a mixed infection. The scar tissue formed in the healing of these ulcerations may give rise to distortion or stricture of the bowel. The ulceration may involve the appendix, and it may be limited to the appendix.

The amebae, burrowing deep in the tissues around the ulcerations, get into the bloodvessels and the lymph spaces, and may be carried to the liver, and there produce the so-called tropical liver abscess. Councilman and LaFleur were of the opinion that the amebae traveled directly through the peritoneal cavity to the liver. The abscess contains necrotic material which is usually bacteriologically sterile; the walls of the abscess are ragged, and consist of necrotic liver tissue which contains amebae. Outside of this necrotic layer is a layer of infiltration, and outside of this, the normal liver tissue. Here, as well as in the intestine, the infiltration is due to proliferation of the connective tissue cells, and there is an absence of purulent inflammation, unless there is a secondary infection with pyogenic bacteria. The contents of the abscess are not like bacterial pus—they are composed of necrotic liver tissue, and contain only such leucocytes as were in the tissue which has become necrotic. The process is not so clear in the intestine, as there granulation tissue is formed from the bacterial infection which always occurs. When a liver abscess points, it may rupture into the lungs or the pleural cavity, or it may rupture in any direction and into any structure around the liver.

Symptoms. The disease is usually subacute from the onset. There is slight fever, pain in the abdomen, and diarrhea, with mucus and blood in the stools; but it may be acute in onset, with fever, great prostration, great pain, and frequent passage of bloody, mucous stools. The disease may be very mild, or liver abscesses may develop without there being any symptoms of dysentery at all. Possibly some of these abscesses occur in cases where the ulceration is confined to the appendix, and it is possible that, in the same way, we can account for some of the cases reported in which the dysentery amebae is found in the stools of persons who have no dysentery. Amebic dysentery does not tend to spontaneous recovery, but rather to become chronic, with periods of latency.

Complications. The great danger is liver abscess, which occurs in one in four, to one in ten, or less, of the cases. There may be perforation of the bowel, or peritonitis. Hemorrhage from the bowel may occur as a result of bloodvessels being opened up by the ulceration; but the vessels are usually thrombosed, so that hemorrhage is rather rare.

The diagnosis is made by finding the amebae in the stool. The stool should be fresh when examined, and should be kept warm; otherwise the amebae will not be motile, and it is dangerous to attempt to make a diagnosis of amebae, in the fresh state, unless ameboid motion is seen. Swollen epithelial cells, or swollen connective tissue cells, may have the appearance of amebae. Unless ameboid motion is seen, smears should be made and stained for study in the ordinary way. In case of doubt, the material may be fed to, or injected into the rectum of young kittens. In liver abscess, besides, the physical signs of abscess, the leucocytes usually run from 18,000 to 20,000, while in uncomplicated amebic dysentery they run from 10,000 to 12,000. If the abscess ruptures into the lung, there is a chocolate colored sputum containing amebae.

Prognosis. The tendency to relapse is characteristic. The great danger is liver abscess, and, in the tropics, the mortality from amebic dysentery and its complications runs as high as sixty per cent.

Treatment. The patient is to be put to bed and placed on a liquid diet. For years ippecac has held its place as the most satisfactory remedy in the treatment of amebic dysentery, and all other treatments have been tried merely to find a substitute, on account of the difficulty attendant upon the giving of ippecac. Vedder undertook to find out what principle in ippecac was active against amebae. He found that emetine killed culture amebae in very high dilution, and that deemetinized ippecac had no special action against culture amebae. Some specimens of emetine killed amebae in higher dilution than did other specimens, and Vedder considered that this depended on a difference in the amount of emetine in different preparations. Some preparations of emetine are a mixture of two alkaloids, emetine and cephaeline. The alkaloid emetine is the principle which has a special action against amebae. The amebae are deep in the tissue; so, a drug, in order to get to them, must be carried in the blood. Rogers treated a series of cases of amebic dysentery and liver abscess with emetine hypodermatically, and found that the dysentery was cured promptly, and that no nausea resulted from the use of the drug. Other observers have used emetine with uniformly good results, though some of them believe that the emetine is to be pushed...
until slight nausea results. One case of liver abscess, draining through the lung, has been reported, in which there was prompt recovery following the administration of emetine.

One must be sure that he has a good preparation of the drug, and it is to be given subcutaneously or intravenously. Baermann and Heinemann suggest that the treatment begin with one or two intravenous (in 100 c.c. of physiological salt solution) or subcutaneous injections of 150 to 200 milligrammes, followed, in the course of eight or ten days, by four or five subcutaneous injections of 100 to 120 milligrammes at intervals of two or three days. These authors consider that some ameba, deep in the tissues, may escape the action of the emetine, and that the ulcers may heal over these ameba. These amebae may remain for days or months, and then start up the process again, and in this way ameba may reappear in the stools from ten to seventy days after the first treatment. On this account, the stools must be watched for months, and treatment is to be repeated at intervals of three or four weeks. Baermann and Heinemann found that the emetine killed the ameba in the tissues, and that the ulcers healed, even in the severe cases which terminated fatally. The cysts are not directly destroyed by emetine, and there are some strains of ameba that are emetine "fast."

The treatment generally advised for liver abscess is prompt opening and drainage. Rogers advises emptying the abscess through a cannula, injecting one grain of emetine, dissolved in an ounce of water, through the cannula before it is withdrawn, and sealing the opening with collodion. He believes that most abscesses will heal promptly with this treatment, and will not require drainage to be left in. Emetine is to be given subcutaneously or intravenously at the same time.

Bacillary dysentery, also known as epidemic dysentery, frequently occurs in the tropics in the form of extensive epidemics. It also occurs in epidemic form in subtropical countries; and in temperate and cold countries sporadic cases occur from time to time, and at times epidemics prevail, especially in armies and institutions. During the civil war, the federal army had 285,000 cases of dysentery. Epidemics prevail in Japan, especially in the summer and autumn. In 1899 there were 126,000 cases in Japan, with 27,000 deaths. Bacillary dysentery is caused by the dysentery bacillus, of which there are two groups—the Shiga-Kruse group and the Flechner group. There are several strains in the Flechner group. The Shiga-Kruse group causes a severe disease, with a mortality of twenty to thirty per cent., or even fifty to sixty per cent. The Flechner group, which is the one commonly met with in the United States, generally causes a milder disease with a lower mortality; otherwise, the morbid anatomy, symptoms, and treatment are the same for both groups.

The morbid anatomy of bacillary dysentery is that of an acute inflammation of the mucous membrane of the large intestine. The mucosa is swollen and intensely hyperemic, with spots of hemorrhage scattered through it. There is usually a superficial necrotic layer, which can often be brushed off with the finger, but there is no ulceration (Fig 2). When the process is severe, all coats of the large intestine may be involved, and the mucosa may become extensively necrotic or gangrenous. The process often involves the ileum, showing a hemorrhagic mucosa with superficial necrosis. In subacute cases the solitary follicles are much swollen; there is less necrosis; and, while there are no ulcers, there are superficial erosions (Fig. 3).

Symptoms. After a short incubation period, the disease sets in rather suddenly with moderate fever, pain in the abdomen, and frequent passages of bloody, mucous stools. The disease runs its course like any acute infectious disease, and, in cases of moderate severity, the symptoms become less severe, and in from ten to twenty days the patient is convalescent. In severe cases the stools may contain sloughs of necrotic tissue; the patient becomes intensely intoxicated, passes into delirium and dies. The disease may be subacute, and last for months.

Complications are rare. Joint swellings are not uncommon in some epidemics. Peritonitis, per-
foration of the intestine, and liver abscess are rare. Neuritis is not a very uncommon complication.

**Diagnosis.** The dysentery bacillus can commonly be isolated from the stools from the beginning of the disease. The bacillus is present in the superficial layers of the affected intestine; it does not commonly get beyond the mesenteric lymph nodes, though it has been found in the bloodstream. After about four or five days the patient's blood serum agglutinates laboratory strains of the dysentery bacillus; and the serum agglutinates both groups of the organism, regardless of which group the infecting organism belongs to. To determine to which group the infecting organism belongs it is necessary to isolate the bacillus from the patient's stool, and to test it out on sugar media and by agglutination with specific sera from immunized animals.

**Treatment.** No medicine influences, directly, the course of the disease; and, as it is ordinarily a self limited disease, the principal indications are to support the patient. Ipecac does not have any specific action, such as it has in amebic dysentery. Serum therapy has been employed with very satisfactory results. Shiga prepared a serum, which he was able to cut down the mortality from the disease in Japan from 35.4 per cent. to 10.8 per cent. Rosenthal prepared a serum that was both antitoxic and bactericidal, and this serum was used, with good results, in the hospitals in Manchuria during the Russo-Japanese war. Vaillard and Dopter, at the Institut Pasteur, prepared a serum which is both antitoxic and bactericidal. Using their serum in a series of over five hundred cases—of which 150 were severe and thirty-two were considered clinically as almost hopeless—they had a mortality of only 1.3 per cent. The serum is difficult to prepare, as small animals are not suited to immunization against the Shiga-Kruse group, on account of its great toxicity; and great care is necessary in immunizing the horse, as tolerance for the organism seems never to be acquired. Vaillard and Dopter do not consider it necessary to have a polyvalent serum, as a serum prepared by immunization with the Shiga-Kruse group of bacillus seems to act equally well against both groups of the organism. It is important to begin treatment early, and the dose of the serum varies from twenty to 100 c. c. daily. When the disease becomes chronic, local treatment of the intestinal mucosa, by irrigation, is important.

**Conclusion.**

We may sum up the important points in the two types of dysentery in a few words:

Amebic dysentery is endemic and does not ordinarily give rise to epidemics; bacillary dysentery gives rise to extensive epidemics.

Amebic dysentery is due to a protozoon; bacillary dysentery is due to a bacillus.

In amebic dysentery the process begins in the submucosa, from the specific tissue destroying property of the ameba which have traveled in through the mucosa; bacillary dysentery is a diphtheritic or croupous process, involving the intestinal mucosa, and the submucosa is only secondarily involved.

Liver abscess is a frequent complication in amebic dysentery; it is very rare in bacillary dysentery.

Amebic dysentery tends to become chronic, with amebic relapses; bacillary dysentery is a self limited disease, with a tendency to complete recovery.

Ipecac, in the form of emetine, is specific in amebic dysentery; a specific antitoxic and bactericidal serum gives the best results in the treatment of bacillary dysentery.

**ACUTE INFECTIOUS JAUNDICE IN CHILDREN.**

**By Charles Herrman, M.D.,**  
New York,  
Attending Pediatrician to the Lebanon Hospital and to the Beth David Hospital; Instructor in Pediatrics, Columbia University.

In this paper I desire to emphasize the fact that there is a form of jaundice which occurs in children which has all the characteristics of an acute infectious disease. Many of our textbooks still speak of this disease as a gastrohepatitis due primarily

---

*Read at the annual meeting of the American Pediatric Society, Washington, May 5, 1913.*
to indiscretions in diet. The infectious material, as yet unknown, seems to have an affinity for the bile passages in the same sense that the typhoid bacillus has for the follicular structures in the intestines.

The following report is based on ninety-eight cases seen during the last six years, chiefly at the Vanderbilt Clinic and at the Lebanon Hospital Dispensary. Twenty-five were seen during October, November, and December of 1912 and January, 1913. These were studied more carefully, and it is on them that the following data are chiefly based.

Age incidence. (Chart 1.) In the series of ninety-eight cases there was no patient under one year of age. The disease is exceedingly rare in young infants. Between one and two years the disease is uncommon—only two patients in ninety-eight. It is most common between the age of three and six. After that the number gradually diminishes.

Seasonal incidence. (Chart 2.) It will be immediately noted that the disease is especially prevalent during October, November, and December, over one-half of the cases occurring during these three months. This fact alone would be a strong argument in favor of its infectious nature. Indiscretions in diet are certainly not more common in October and November. In Chart 2 I have added the curve of seasonal incidence drawn from the figures given by Flesch in a series of 188 cases recorded as occurring during a period of ten years at the Stephanie Hospital in Budapest. It will be seen that the curve corresponds very closely to my own. Several authors have noted that the disease is more prevalent when the autumn and winter are mild. This would hold true for our epidemic of last year in New York city.

In none of the last series of twenty-five cases was I able to ascertain that there had been any gross indiscretion in diet just previous to the attack, and in only three of the patients was there a history of previous attacks of indigestion which might indicate a predisposition. If the disease was dependent upon digestive disturbances we should expect it to be more common during the summer months, a time when, as the chart shows, the fewest cases occur. The disease is rare in infancy, when gastrointestinal disturbances are most frequent. Even when the duodenum is markedly affected, jaundice does not result. In several of my patients there was no digestive disturbance at any time during the attack, and in ten of the last twenty-five, after the disturbance at the onset, the appetite was good and there was apparently no change whatever in the digestive functions. The vomiting which is frequently present at the beginning is probably toxic.

Bacteriology. The specific microorganism, if there is one, which causes this disease, has not yet been isolated. Jaeger, in a case of Weil's disease, found a Bacillus proteus fluorescens. Bantir cultivated from the blood obtained by puncture of the spleen a capsulated bacillus which he called Bacillus icterogenes. Jaeger considered this identical with the one he had described. Possibly the examination of blood cultures and duodenal contents obtained by aspiration, by means of the duodenal catheter, may throw more light on the etiology.

Many authors have considered it most likely that the infection takes place through the digestive tract, on account of the initial gastric disturbance and the connection between the duodenum and common bile duct. However, this is not conclusive. From the fact that climatic conditions seem to play such an important part in the seasonal incidence of this disease, it is not unlikely that the infection takes place through the nasopharynx.

Onset. The most frequent symptoms at the onset were headache, lassitude, and anorexia, with vomiting and some rise of temperature. In only three of the last twenty-five cases was it distinctly stated that the patient had no fever. In thirteen there was vomiting, in eight no vomiting, and in the remaining four vomiting occurred once after the taking of a dose of castor oil.

Symptoms. Fever. At the time of observation the temperature was normal in six patients, from 99° to 100° F. in eight, from 100° to 101° F. in eight, and over 101° F. in three. As three of the six patients with a normal temperature were seen four or more days after the onset, it is not unlikely that they may have had some rise of temperature previously.

Pulse. In none of the patients was the pulse slow. This peculiarity of the pulse in the jaundice of children has been pointed out by a number of observers. In those patients who had a distinct rise of temperature the pulse was correspondingly in-
HERRMAN: INFECTIOUS JAUNDICE IN CHILDREN.

[New York Medical Journal]

creased. This may be due to the infectious character of this form of jaundice, as against other forms of obstructive jaundice more common in the adult.

Pain in the abdomen or epigastrium was noted in ten of the twenty-five patients; pain in the legs in three.

Urine. The urine became darker on the first day of the disease in two patients, on the second day in two, on the third in nine, on the fourth in five, on the fifth in three, and on the sixth day in two patients. In the remaining two the day was not noted. The color of the urine returned to the normal in one week in eight patients, in two weeks in eight, and in three weeks in eight patients. In one the time was not noted. In three cases the examination of the urine showed traces of albumin, but no casts. The color of the urine was found to give the most convenient method of determining the improvement in the jaundice. The exact color of the stools is not easily determined, and their offensive odor makes it disagreeable for the parents to bring them. The conjunctiva remains yellow long after the improvement has begun. The method employed was as follows: Five small vials numbered 1, 2, 3, 4, 5, were used. Number 1 contained a yellow liquid of the color of the average normal urine, and in numbers 2, 3, 4, 5 there was a yellow liquid of increasing depth of color. The urine of the patient was compared with these. In this way the improvement could be readily followed and the return to the normal ascertained.

Stools. The clay color of the stools was noted on the second day in six patients; on the third, in three; on the fourth, in three; on the fifth, in three, and on the sixth day in six patients. In four the day was not noted. As is well known, the light color of the stools is largely due to the presence of undigested fat. If fat is excluded from the diet the stools lose the characteristic clay color. The stools became normal usually at the end of two weeks. In twelve patients the bowels were regular; in four there was diarrhea, and in eight, constipation. In almost all the patients the appetite was poor at the onset, but after the initial disturbance had passed, the appetite was good in one third of the patients. The conjunctiva was noted to be yellow on the first day in two patients; on the second, in four; on the third, in six; on the fourth, in six; on the fifth, in two, and on the sixth day in two patients. The day was not noted in the remaining three. The color returned to the normal, on an average, at the end of the third week.

Itching was present in eight. These were the patients in whom the jaundice was the most pronounced.

Liver. The liver was palpably enlarged in twenty-one, and normal in only four. It was felt one finger below the costal margin in the mammary line in four; two fingers in twelve, and three fingers in five. In no case was it distinctly painful to palpation. With the improvement in the jaundice it gradually diminished in size, but was still palpable after the jaundice had entirely disappeared.

In six patients examined three or more months after the attack the liver and spleen were no longer palpable. In no case was it possible to palpate the gallbladder.

Spleen. The spleen was palpable in ten patients; not palpable in fifteen. It returned to its normal size much more rapidly than the liver.

All but one patient recovered. Only one had a serious complication, namely, an otitis and mastoiditis which required operation.

The one fatal case which occurred in the midst of the epidemic was in a girl of twenty months, who was admitted to the Lebanon Hospital on November 30, 1912, at 10 a.m., and died four hours later. The family history was negative. There were several other healthy children. The patient had never had any acute infectious disease, the only sickness having been an attack of intestinal indigestion three months previous, which lasted about two weeks, from which the child made a good recovery. Twelve days before admission to the hospital the child had fever, vomited several times, and had slightly greenish stools. One week before admission, that is on the fifth day of the disease, the mother noticed that the urine was dark in color.

I examined the child one hour before she died. The temperature was 103.2° F., the pulse 160, and the respiration 60. She was already comatose. The conjunctiva was yellow. The liver was two fingers below the costal margin in the mammary line, and the spleen one finger below in the axillary line.

An examination of the blood showed white blood cells 32,000; ninety-five per cent. polymorphonuclear leucocytes. The urine obtained with catheter was acid, with a specific gravity of 1.020; dark yellow in color, with a yellow foam; albumin examination, positive; sugar, negative; white blood cells, red blood cells, and many hyaline, granular, and epithelial casts were present. This patient presented all the symptoms of a severe infectious jaundice, a type which is usually spoken of as Weil's disease. Except for its severity it was in no way different from the milder cases. An autopsy was not obtained.

Treatment. When the appetite is fair, as it is in many cases, it is only necessary to restrict the amount of fat in the diet. Soup, lean meat, vegetables, skimmed milk, and bread may be given. It has been customary to give so called cholagogues, but experiment has shown that most of these drugs have little or no cholagogue action. Whatever good effect is obtained is due primarily to an increase in intestinal peristalsis. In any cases the indication is not to increase the secretion of bile, but to facilitate its passage through the common bile duct into the duodenum. An increased secretion without a proper outlet would be rather a disadvantage. Bile is secreted continuously, but when the stomach is empty there is no flow of bile into the duodenum; it is stored up in the gallbladder. When the acid chyme from the stomach passes into the duodenum it reflexly stimulates the gallbladder to contract, the sphincter at the outlet of the common bile duct relaxes, and bileushes into the duodenum. Some years ago a member of my family had a permanent biliary fistula following an operation on the gallbladder. It was noted that very little bile flowed from the fistula during the day, and very
much during the night. During the day the regular ingestion of food caused the gallbladder to empty its contents into the duodenum. At night no food was taken; the bile was stored in the gallbladder, and flowed out through the fistula. The amount of bile passing out through the fistula was easily reduced by giving a small meal late at night. In a paper published in the New York Medical Journal for September 22, 1906, I suggested that this method of giving small frequent meals might be applied in the treatment of certain biliary diseases, including infectious jaundice. Some years ago Gerhardt suggested that in come cases the distended gallbladder could be felt, and its contents expelled by pressure. The gallbladder is so rarely palpable that this is practically impossible. However, the same result may be obtained by the giving of small, frequent meals. The character of the food is of secondary importance. I usually give five or six small meals a day, the two or three additional ones consisting of a sandwich and a glass of skimmed milk. By the use of this method I believe I have been able to shorten the duration of the disease.

RETROCALCANEAN BURSITIS.*

By Charles Stanley White, M. D.,
Washington, D. C.,
Associate in Surgery, George Washington Hospital; Associate Visiting Surgeon, Emergency Hospital.

There are several affections peculiar to the heel, the most interesting of which is inflammation of the bursa between the os calcis and the tendo Achillis. It has come in for very little consideration at the hands of pathologists or surgeons for the very simple reason that the disease is uncommon. Anatomists have noted the presence of the bursa for a very long time, and have taken into account two other bursae in the immediate vicinity, besides a great many throughout the body. The fact that there are almost innumerable bursae in the entire body has probably discouraged investigation along the clinical side, as the statement that seventeen exist in and about the elbow joint would tend to remove any tendency toward a systematic study of bursal affections. The literature in textbooks, and even of special articles, upon the retrocalcanean bursa has been scant, and an accurate description has not been found available by the author, who supplemented by dissections such descriptions as were obtainable in a survey of literature in the Surgeon General's Library. No attempt is made to treat the subject exhaustively, and it is hoped that others with more time, patience, and scientific attainments will continue it.

Albert, of Vienna, in 1893, described the inflammation of this bursa, and it was promptly, but improperly, named Albert's Disease. Retrocalcanean bursitis and achillodynia are terms used synonymously. Albert dwelt upon trauma as the cause, and opined that it was cellulitis about the tendon, or even a periostitis; laying little or no stress upon the part played by the bursa. It remained for Max Muller, of Berlin, with true German persistency, to fix the pathological responsibility upon the bursa, which he did by injections and incisions into the bursa.

The normal bursa is difficult to demonstrate as an anatomical structure, and even histologically it often seems rudimentary, as the endothelial lining is not always apparent. It measures about one inch in its vertical diameter, three fourths of an inch transversely, and about one eight inch in thickness. Its superior pole is on a slightly lower level than the upper border of the os calcis. It is encased in fat, from which it may be difficult to differentiate, and lies between the os calcis and the tendo Achillis, containing within its walls a small quantity of clear fluid. The sac is very delicate and is said to be derived from the periosteum and sheath of the tendon, but this is largely theory. The bursa becomes a very concrete object in its inflamed state, and bears little resemblance to the frail sac of the normal (all walls and fluid having become magnified many times) and it is then designated a bursal cyst or hygroma. Rossale found few normal bursae in 225 dissections.

The causes of retrocalcanean bursitis, as it should be termed, have been elucidated, and chief among the etiological factors is trauma, acute or chronic, appearing as ill fitting shoes, irritation by excessive walking, bicycle riding, resting the limbs upon the heels, and certain occupations which tend to produce pressure at this point. Infection through a break in the epithelium is possibly an exciting cause. More remote agencies are tuberculosis, gonorrhea, rheumatism, and the infectious diseases; but these are of a decidedly minor importance. Flat foot has naturally come in for its share of responsibility in producing the disease, but it is more often an accompaniment than an originator. Physiologically, it may be said that irregularities of the os calcis, more particularly those cases having a small spine posteriorly, have played a part, but the x ray has demonstrated so many deviations in bone contours that this is almost a negligible factor. Briefly stated, the pathology is that of hyperplasia of the capsule and excessive secretion. The bursa never reaches the great size of a housemaid's knee, and one the size of an almond may be considered large.
According to Tubby, a hygroma may undergo any of the following changes:

a. Hemorrhagic degeneration.
b. Fibroid degenerations.
c. Tuberculous infection.

While the symptoms are typical if understood, an attending flatfoot is likely to be indicted for the condition. The physician is consulted because the patient has pain about the heels, more especially at night. This is usually relieved by rest over night, only to return each evening, if he is up and about, as walking provokes pain, and he may be nearly incapacitated for this reason alone. After the disease has lasted for a few weeks or months, the pain no longer remains confined to the heels, but radiates up the leg and down the sole of the foot. The gait is typical and is just what may be expected if our conception of the pathology is correct. If the patient is directed to walk barefoot, he will take short steps and keep the weight largely upon the ball of the foot, the heels scarcely touching the floor. In other words, he keeps the foot in plantar flexion, as much as possible, because dorsal flexion, such as is employed in a long natural stride, compresses the swollen bursa and elicits pain. The patient naturally walks in the most comfortable way, namely, on the anterior portion of the foot, and if he is directed to walk upon the heels it is painful, if not impossible. The history, then, will be pain in the heel, extending to the calf and sole, worse during the day, aggravated by walking, with relief at night, insidious in its onset, and extending over a long period. An inquiry into the patient’s habits may furnish a clue in the way of bad shoes or too much walking. Acute trauma is uncommon.

Between the os calcis and tendo Achilles swelling is visible and palpable. It is moderate and symmetrical, shades off into the surrounding tissue, and it is difficult to determine either by the eye or finger its exact limitations, so closely is it in contact with the tendon and bone. It has not the fixation of a bony growth nor the pseudo fluctuation of a fatty tumor, but appears to be of the same density and mobility as a ganglion. In the suppurative type fluctuation is present. Pressure upon the bursa causes pain, but this can be brought out in another way, namely, by grasping the heel with one hand and flexing the foot dorsally with the other. This movement brings the tendon and os calcis closer together, compresses the bursa, and elicits pain, just as though the bursa had been compressed between the fingers. The swelling varies from time to time, within moderate limits, the exacerbations probably depending upon the abuse or misuse of the part.

The persistency of the affection has been known as long as the disease has been described; in fact, this is a conspicuous symptom, noted by Albert and others. It also tends to recur. Rest has proved beneficial and in many instances curative, but the prolonged, though successful treatment by this means is offset by the pecuniary loss to the patient and the proclivity to relapse. Local applications in infinite variety have been used, but iodine and ichthyll have withstood the ravages of a kaleidoscopic materia medica. Incision and drainage and injection of iodoform emulsion are two methods that have slowly succeeded in reducing the bursa to its outer vestments only. The author believes the rational surgical treatment is complete removal of the bursa, an operation simple in its execution and prompt in its results.

Operation:—Probably the best method of cleansing the area is by the older process with green soap, alcohol, ether, and mercury bichloride the night preceding the operation and also on the day of the operation. While the bursa is equally accessible from either side, the inner side is preferable for the reason that the scar is less exposed to view and less likely to be traumatized. The skin is divided three inches between the tendo Achillis and the os calcis, with the centre of the incision over the greatest prominence of the bursa. With the hold in extreme plantar flexion, the tendon is relaxed, and retraction of the skin, fat, and fascia facilitated; exposing the hygroma, which, in the inflamed state, is easily seen. With scissors and slight traction with dissecting forceps the bursa can be removed without injury to any important structure. Should the sac be indistinct, the fat between the bone and tendon should be removed, as this will include the bursa. It is true that at times it may be almost concealed by lipoid tissue, but usually it comes into view as soon as the proper retraction is made. It is not uncommon to find the superior posterior angle of the os calcis quite sharp, almost
spineots in type, and it may be rounded off with an
ostectomy, though this is not at all necessary.
Little or no hematomasis is required, and the wound
is closed without drainage, and the foot then placed
in slight plantar flexion, a starch or plaster bandage
being used to retain it so for about eight days, at
the end of which time the dressing should be
changed, passive motion started, and the foot
allowed to resume a natural position. The patient
should be allowed to walk at the end of twelve or
fourteen days, but this will be painful for a while.
At the end of three or four weeks recovery is usu-
ally complete.

The following case was referred to me by Doctor
Whitson, of Washington, and was the first I have
-treated by the method outlined in this paper:
G. B., aged twenty-five years, male, salesman. His family
history is negative, especially with reference to tuber-
culosi in its commoner forms.
Previous history: He had pneumonia at the age of ten
years and again at fifteen years, making a good recovery
in each instance. He has never had venereal disease.
Present illness: In May, 1910, he complained of stiffness
about the heels and ankles, but which improved a
little after walking. His occupation kept him on his feet,
but the improvement was of short duration, and he soon
found that exertion increased the pain and produced a
slight swelling just anterior to the attachment of the
tendo Achillis. In July, walking became painful to such
a degree that it was almost unbearable. He then con-
sulted several physicians, and for the following year was
treated for rheumatism, neuritis, and flat foot, without
improvement. When examined in August, 1911, he showed a
distinct swelling over each retrocalcanean bursa, with
tenderness upon pressure. His most comfortable gait was
a short step, and upon the toes. A long stride was in-
tolerable. On August 21st, both burse were removed
under a general anesthetic. He was kept in bed two
weeks, with the feet in slight plantar flexion by a light
cast. Three weeks later he was able to walk in com-
fort, and has not been incapacitated since.

A COMBINED CYSTOSCOPE AND
EVACUATOR.

By E. MacD. STANTON, M.D.,
Schenectady, N. Y.

It is the object of this paper to describe a simple
attachment designed by the writer for the purpose
of coupling a Bigelow evacuator to a direct vision
(Braasch) cystoscope so that the evacuation of
stone fragments may be visually controlled. Expe-
rience has also shown the attachment to be very
useful for the evacuation of blood clots and other
substances not easily removed by simple irrigation.
Since the development of practical lithotrites by
Weiss and Costello, in the early part of the nine-
teenth century, the crushing and the cutting opera-
tions for the removal of stone in the bladder have
both had their advocates, and since the introduction
of litholapaxy by Bigelow, in 1878, the majority of
genitourinary surgeons have preferred litholapaxy
in cases with a crushable stone. This operation has
always been accompanied by a lower mortality than
lithotomy, and, taken as a whole, the end results of
the crushing operation have been as good or better
than those obtained by lithotomy; but the fear of
leaving fragments of stone in the bladder, to form
the nidus for the formation of new stones, has led
many surgeons to practise the more dangerous op-
eration of lithotomy.

The development of cystoscopy has made it
possible to control the results of the litholapaxy, but
this necessitates the intro-
duction of a third instru-
ment, the cystoscope, into
the bladder, and if there are
stone fragments found, the
 evacuator must be again in-
 troduced and the whole
 process repeated. The ad-
 visability of combining two,
or possibly all three, of the
 instruments into a single in-
 strument has long been rec-
 ognized, as evidenced by the
 evacuating Lithotrite of Chis-
 more, the cystoscope lithotrites of Xitze, Casper,
and Walker, and the more recently described evacu-
ating cystoscopic lithotrite of Young.

From a purely practical standpoint these instru-
ments are either too complicated, or lacking in the
necessary strength, or they are too expensive to per-
mit of general use by those called upon to remove

vesical calculi. Conditions approaching a practical
ideal are reached, however, if, after crushing and
evacuating the stone by the method of Bigelow, we
can control our work with the cystoscope, and, if
fragments are found, remove them through the tube
of the cystoscope under visual control.

The instrument here illustrated was devised with
this end in view. After crushing the stone with a
of the bacilli may occur from auto-infection through (a) natural proliferation of bacilli and toxines engendered; (b) traumatic injuries, such as lacerations, contusions, luxations, and fractures; (c) intercurrent fevers; (d) intemperance and debauches with usual concurrent exposure; (e) natural susceptibility or some acquired through loss of body tone; (f) in females, pregnancy.

We must now revise our old ideas regarding the invasion and development of leprosy. Thin, in his textbook on leprosy, says: "When the parasite has established itself in the skin, the first effect—before there are any changes observable to the eye—is to set free a poison which produces more or less marked results in different individuals, causing the so-called prodromata or premonitory symptoms of leprosy," and Impey (1806): "The poison enters the blood, and in addition to setting up the premonitory fever, acts upon the terminal branches of cutaneous nerves, causing vasomotor paralysis of the capillaries, and the consequent formation of erythematous patches in the skin."

In American Medicine, October, 1907, the writer said:

Cases are found in which exposure in the most adequate way has not infected the person concerned who, a few years later, falls a victim to a slight contact. It has been our error, I think, to suppose these cases to be incubatory. There is no chance or freakish happening in the natural world; and all is the result of cause and effect. We shall find, no doubt, that when the germ of leprosy is properly introduced into the ready soil, it will grow according to regular specific laws. It is not according to the working of other laws of exposure to disease to suppose for a moment that the Bacillus lepra will remain quiescent in the tissues for ten, twenty, or, perhaps, sixty years, as some authors state. On the other hand, its incubation is probably short if the conditions are favor-
able. While I will indulge in no hopes not based on actual data, and make no statements which cannot be substantiated by investigation, I can safely say that the line of work to be carried out is plainly marked already and will be completed within a few years.

The modus of infection and systemic involvement is now for the first time made plain, and immunity and nonimmunity explained, as well as the long or short "incubatory" period. Also the occasional subject in whom the disease was "self limited," with local lesion, some subsequent alteration of tissue, and final readjustment to normal condition or cure. Such cases have been called "latent" here. I have a patient now with contractures and other unmistakable evidences of leprous damage, who is entirely well, the leprous invasion having stopped without therapeutic intervention of any sort. The man has had absolute freedom as a citizen for the last nine years.

Since 1902 Doctor Goodhue has been making use of every reasonable therapeutic measure for the amelioration and possible cure of the lepers under his care, reporting regularly upon his work. Doctor Hollman, also, while assistant at the settlement, made some valuable reports on the progress of his work there, with, however, no definite results as to cure. In 1906 Dr. J. T. Wayson, in charge of the receiving station at Honolulu, and Doctor Reinecke at the U. S. Leprosy Investigation Station, reported upon the palliative treatment of leprous rhinitis. During the same year Dr. Walter R. Brinkerhoff and Dr. J. T. Wayson made a report of their use of natin in the treatment of leprosy, concluding as follows: "In our hands the administration of natin to six cases of leprosy gave slightly encouraging results in two cases. In one of these the lesions decreased in extent and took on a focal character. In the other case a tubercle disappeared during the treatment. Four patients seemed unaffected by the treatment, even when persisted in for over a year. Constitutional reactions were only seen when the dose was large. No local reaction or puriform softening of the tubercles was observed."

Doctor Hirshberg, of Johns Hopkins University, in a lay journal published last June, reports on the work of Dr. J. Williams Lord before the college skin clinics, stating that a cure had been affected in leprous cases by the use of the "snow" pencil—"the ordinary carbonic acid gas, compressed into a solid pencil, an accepted method for removing warts and recognized for many years in the treatment of less serious skin troubles."

"Pressed a bit at a time," continues the author, "from the tube and placed upon the skin, it has somewhat the same effect as radium, but in this instance it is the extreme cold that destroys the diseased tissues and germs and thus cures the trouble; for, as it melts, the temperature about the infected zone falls to a very low degree of temperature. Besides this local treatment the cure includes a cleansing of the patient's system by internal administration of chaulmoogra oil." Doctor Hirshberg says that the experiments have been carried on since 1895 in a leper woman who came to the clinics at that time. One would not expect much definiteness or scientific accuracy in an article for popular reading, but the matter is interesting. The medical superintendent of the Molokai Leper Settlement, after
having tried the internal treatment by chaulmoogra oil, and the use of sulphur baths, for many years, has made exhaustive reports upon the same, finding them both of use as ameliorative measures. In 1910 Doctor Wayson made use of the "snow" pencil, and by what he calls the "freezing" method has met with success in the treatment of leprous lesions. And although his results have met with some criticism and his one or two "cured cases" not been recognized generally, the work has been valuable, particularly to those who were of the opinion that leprosy is a localized lesion and may, for some time, remain so.

"Leprosy," said Doctor Goodhue in February, 1908, "is a surgical disease. That is to say, the various surgical procedures adapted to the relief and cure of the pathological lesions constantly and necessarily associated with leprosy are of infinitely more service to the leper in the relief of pain and discomfort, prevention of wasting fevers, restoration of active use of the hands, and especially of the feet, and prolongation of life, than all the other therapeutic measures of our present day leprosy therapeutics." A much earlier account says: "As the result of long continued experiments and observations, the medical superintendent of the leper settlement has concluded that there are several useful remedial and palliative methods of treatment, both internal and external. Chaulmoogra oil and eucalyptus have been found ameliorative and are constantly employed. Other methods now being used he believes will, in incipient cases of leprosy, prove a cure."

At the second international conference against leprosy, which met at Bergen in 1909, all treatments of leprosy up to this date were summarized and discussed. Von Deycke, of Hamburg, reported on his experiments with nasin. "In a large per cent of cases treated with nasin an improvement was observed in the general conditions and local symptoms, and apparently the further development of symptoms was arrested," he said. Doctor Kiwull, of Russia, in a report of his experiments, stated that "improvement of general symptoms and the leper process was noted in three cases. In six no notable improvement of general condition was observed, though two of the patients said they felt better. A very decided change for the worse was seen as regards general symptoms, and also to some extent in objective findings in the case of five patients." Doctor Lie, of Bergen, declared that the nasin treatment of Doctor von Deycke was "not specific treatment," Beurmann, of Paris, read an important essay, in the course of which he said:

That the skin is the usual site of infection and that the nares are more rarely so; that when the baelli gain entrance they remain dormant for a certain time and then, under certain unknown conditions, gain sufficient virulence to multiply and cause an inflammatory reaction in the surrounding tissues. This constitutes the initial lesions of the disease. In other words, the first leprous nodule that appears represents the point where the infection was received months or years before. Later these baelli reach the blood stream and are carried to distant parts; after another quiescent period of undetermined or indefinite length, they cause an inflammatory reaction in the localities where they have found lodgment, and a crop of secondary lepra tubercles appears. Leprous baellemia is a common occurrence in the course of the disease.

Of this Dr. D. H. Currie, a delegate to the conference, said in his paper before the Hawaiian Medical Society, November, 1909:

If Doctor Beurmann is correct regarding the appearance of the first nodule at the site of the infection, then there must be a stage, of variable length of time, in which leprosy is a local disease, and incision of this first papule or nodule should arrest the further progress of the disease. While we do not endorse this theory, still it might be worth while for practitioners in leprous countries to excise all single papules or nodules when in doubt as to their nature, and submit them to a laboratory for examination—such a procedure would be of diagnostic aid, and if Beurmann is correct, would be of the greatest service to the patient.

It is to be regretted that Dr. W. J. Goodhue, who also was appointed as a delegate to the conference, did not go and state his opinion, based upon the surgical removal of leprous lesions at Molokai since 1902.

The supposed primary lesion in the nose has been found to be secondary to the local infection elsewhere, as with syphilitic symptoms from a primary chancre. In my opinion the result obtained in the case of P— is one of the most important and far reaching for many a day. It means that we must abandon our old theories regarding the development and curability of leprosy. In every case, probably, of suspected infection, an early removal of the involved tissue will cure the disease; many cases of long standing will be amenable to surgical treatment, and specific knowledge, now at hand, will enable us to avoid infection to a great extent.

THE USE OF A VERY MINUTE INITIAL DOSE IN TUBERCULIN THERAPY.*

By MYER SOLIS-COHEN, A. B., M. D.

Philadelphia, Pediatrist, to the Jewish Hospital and to the Philadelphia Jewish Sanatorium for Consumptives, Eagleville, Pa.; Assistant Visiting Physician to the Philadelphia General Hospital; Consulting Physician to the Home for Consumptives, Chestnut Hill, Pa.

That in tuberculin lies the future of phthisis therapy seems to be the universal opinion among tuberculosis workers. Those who have used this remedy at all extensively are as a rule convinced that it is an agent of considerable value, although all have seen disastrous consequences following its use. Even when a statistical comparative analysis of patients taking tuberculin, and those not taking it, shows only slight or even no definitely demonstrable advantage in its employment, there usually remains a general impression that tuberculin is of value. This is probably due to the clinical observation of remarkable benefit in certain cases undoubtedly directly attributable to the administration of tuberculin. Well remembered, unfortunate experiences, on the other hand, may cause some to regard its use as unjustified. It should be the constant endeavor, it seems to me, of those who have opportunities for studying this remedy, capable at

**From "Leprosy," reported in Louisiana, by Dr. Isadore Wyor, 1912.

Six patients reported by Doctor Rice, of Hawaii, to be cured are found to be lepers by the Board of Health, 1906.

*Read before the Philadelphia Clinical Society, May 5, 1913.
once of so much good, and so much harm, to study how the harmful effects may be avoided.

The one great source of danger, in my opinion, lies in the size of the initial dose as ordinarily given, which I believe to be one thousand times too large. It is true that the customary initial dose of 0.0001 to 0.001 milligramme has been given to tens of thousands of patients without producing a recognized reaction, but it is equally true that the much larger initial doses given when Koch first announced his discovery were likewise in many instances not followed by a reaction. It is, however, also true that the larger dose of earlier days, and the smaller dose of to-day, have both at times provoked serious reactions, even hastening death. There has been less danger with the smaller initial dosage, and many phthisiotherapeutists are administering to-day an even smaller initial dose than they gave a few years ago. Physicians try to avoid a reaction by selecting their cases, picking out those regarded as suitable for tuberculin treatment. This selection of cases is a recognition of what the good and the bad results of twenty-five years ago, and of to-day, really signify: that tuberculous subjects vary in their susceptibility to tuberculin. Thus, the larger dose can be borne by some and not by others, while the smaller dose can be borne by a greater number of persons, but is still too large for many. But far greater is the number of patients who can take the very minute initial dose that I am advocating, and much, much fewer are the reactions accompanying it. The physician who selects a patient that he regards as suitable for tuberculin treatment is deceiving himself. He is selecting a patient suitable not for tuberculin, but for the dose of tuberculin he administers; and his pronouncing of a patient as unsuitable for tuberculin treatment merely means that experience has shown that that type of patient cannot take with safety the initial dose he ordinarily employs. This same patient might take with safety and benefit a dose one thousand or one ten thousand times smaller. In this connection I desire to suggest the possibility that the benefit and the absence of danger that have been reported from the use of tuberculin prepared from the less virulent tubercule bacillus of branched form, or, which has passed through a cold blood animal, may be due to a diminution in the dose of the active principle in tuberculin, produced by the attenuation of the virulence of the tubercule bacilli used.

The determination of the initial dose is an arbitrary matter. White and Van Novan have devised an ingenious method of measuring a patient's susceptibility to tuberculin, but the initial dose based on this index is an empiric one. The methods suggested by Dürel, and by Strickler and myself, for regulating tuberculin treatment by means of the blood picture are effective only after the first dose of tuberculin has been given.

The initial dose of tuberculin, as administered by different workers at the present day, varies within wide limits. Maraglana gives one milligramme of his extract of macerated tubercule bacilli. Petruschky gives 0.1 milligramme of O. T., and T. R. Bandelier and Roepke give 0.1 milligramme of O. T. to patients in good condition, and 0.01 milligramme if it causes a reaction. According to a similar plan, they gave 0.002 to 0.0002 milligramme T. R., and 0.001 to 0.0001 milligramme B. E. Most all who use tuberculinium purum begin with 0.01 to 0.02 milligramme. The initial dose of Dixon's tubercle bacilli extract is one milligramme, and of his suspension of dead tubercle bacilli 0.001 milligramme, although some of his assistants give 0.0001 milligramme. Hammer begins treatment with doses of 0.01 to 0.001 milligramme of O. T. Calnette gives 0.001 milligramme. C. L. Denys gives 0.0001 milligramme of B. F. Trudeau gives 0.001 milligramme of O. T., and from 0.0001 to 0.00005 milligramme of B. E. Latham and Innan give 0.0002 to 0.0005 milligramme of T. R. Brown begins the administration of B. E., T. R. and B. F. with 0.0001 milligramme for the usual case, and 0.00001 milligramme for the unusual case reacting generally to the former dose. Ringer's initial dose of B. F. is from 0.0001 to 0.00001 milligramme. Solomon Solis-Cohen gives 0.00001 milligramme of O. T., the other preparations being given in larger dosage. Bullock gives B. F. and B. F., beginning usually with 0.000001 milligramme: never with more than 0.00001 milligramme, and sometimes with 0.000001 milligramme. Dürel begins with from 0.000005 to 0.000000005 milligramme. In beginning tuberculin treatment I now give 0.000001 to 0.000001 milligramme of B. F. or O. T. to incipient, afebrile, inactive cases, 0.000001 to 0.00000001 milligramme to patients with moderate fever or moderate evidence of activity, and 0.00000001 to 0.00000001 milligramme to patients with high fever or marked activity. The smaller doses I also give to patients who react unfavorably to 0.000001 milligramme.

How tuberculin acts we do not know. Various ingenious and possible hypotheses have been advanced, convincing, no doubt, to their authors, and to some others who delight in conjecture, and probably comforting to those who like to believe they are familiar with the scientific basis for their action. Speaking simply, and omitting the unknown, we might say that the objects aimed at in tuberculin therapy are do good, and to do no injury; and that the proper dose is the amount of tuberculin that will produce a maximum of benefit with a minimum of harm. These are the requirements fulfilled only by the very minute initial dose of 0.000001 milligramme or less. While different methods of administration are followed in the endeavor to do good, all agree on the way to prevent harm: namely, to avoid severe reactions by giving a small initial dose, increasing the dose gradually, and paying attention to the signs and symptoms of a slight reaction. There can be no question that with the very minute initial dose there is much less likelihood of producing a severe reaction. The question that probably does arise in many minds is whether any effect at all can be expected from so small an amount. My own experience, and that of Bullock and Dürel, prove beyond doubt that 0.000001 milligramme of tuberculin and less can affect both favorably and unfavorably the temperature curve and the subjective and objective symptoms. Whatever method of administering tubercu-
lin be employed, the object sought, I believe, can be better obtained when the initial dose is 0.000001 milligramme or less. Many give tuberculin with the idea of inducing tolerance for the tuberculous toxine, the object being by gradually increasing the dose to finally give the patient a large amount of tuberculin without having caused any reaction during the process. Surely this can best be attained by beginning with a dose that is least likely to produce a reaction. Some increase the dose until they obtain one that reduces the temperature and ameliorates the symptoms, keeping the patient on this dose until it loses its effect, whenupon it is again increased. Unless the maximum initial dose is given, one may begin with an amount too large to produce the effect desired. A third group of tuberculin therapeutists believes that most benefit is derived from a slight reaction, and give just enough to produce this. White and Van Norman determine the amount necessary for this purpose by means of their tuberculin index. Others give a small dose, which is gradually increased until a slight reaction is obtained. These are more likely to obtain this slight reaction, and avoid a severe reaction by beginning with 0.000001 milligramme because in many cases the ordinary initial dose of 0.0001 milligramme produces a severe reaction.

I shall now briefly recite a few typical cases that bear out the above statements as to the beneficial effects of the very minute doses, and the severe reactions they often produce. But first, in contrast, I wish to describe the case of a patient who was able to take the ordinary doses without exhibiting the slightest reaction; for it is experience with this type that makes physicians regard as satisfactory the dose ordinarily employed.

Last July I was called to attend, during an acute exacerbation, a girl of eighteen years, a saleswoman, who for five years had been treated for tuberculosis at the Phipps Institute, Jefferson Hospital, and by private physicians. Because she had been living in the suburbs, there was infiltration of the right upper lobe and of the apex of the left upper lobe. The patient was treated at home for a few weeks and then sent to a boarding house in Collegeville, Pa. She was put on rest and gradually increased the medication consisting of crocote, iodine, starch, and sodium sulphate, reduced iron, digitalin and calcium glycerophosphate. On July 28th the girl was given tuberculin bacilli in emulsion by mouth every seven days beginning with 0.000001 milligramme and increasing the dose gradually. Marked improvement followed the administration of tuberculin. After five weeks in the country the girl returned to her home in the congested portion of Philadelphia and took a position in a store where she worked on her feet eleven hours a day. The tuberculin treatment was continued until March 5th of this year, the last dose being 0.007 milligramme. At no time did the patient show any sign or symptom of a reaction. She is now in good health.

The next case illustrates the type of patient with little involvement and increased susceptibility to tuberculin, which could not be determined beforehand from the symptoms:

A young Russian girl, now about twenty years of age, was attacked with a cough three years ago—six months after coming to this country. She had been a patient of mine at the Philadelphia Jewish Sanatorium for Consumptives, Eagleville, Pa., from March until June, 1912, during which time she gained fourteen pounds. After leaving the sanatorium the patient was without medical attention, and although feeling badly went to work in a mill ten hours a day and became still worse. Her temperature was always 100° F. She came to me last fall to make application for her to some sanatorium, and I volunteered my services gratuitously until she should be admitted. Examination on October 14, 1912, disclosed infiltration of the upper portion of the right upper lobe and a thickened pleura over the apex of this lobe. The next day she was given 0.000001 milligramme by mouth in emulsion. Two hours and a half later her cough became worse; at 1 p.m. headache developed. The patient also suffered from anorexia and malaise, but her temperature was no higher than 99°. Some of these symptoms were ameliorated the following day, but the patient spat two small clots of blood, the first hemoptysis in a month. On November 7th 0.000001 milligramme tuberculin was given by mouth. The cough became worse and the patient was admitted on November 10th. She came blood tinged the first time since October 16th. There was no further hemorrhage until two weeks later, when on the afternoon of the day the next dose of 0.000001 milligramme tuberculin was given the sputum became streaked with blood. Twice daily continued her pleuritic 0.000001 milligramme tuberculin was given and at 2 p.m. that same day the patient spat up a small piece of blood. For the next month and a half the same dose was repeated at biweekly intervals for the following six weeks. The patient had a moderate reaction each time, but without hemoptysis. Then doses of 0.000002 and of 0.000003 milligrammes were given, but as the reaction seemed to severe the dose was reduced to 0.000002 and given thrice weekly for five days. The patient gradually improved and grew stronger, and last March entered the training school of the Home for Consumptives, Chestnut Hill, where she is working hard as a nurse and keeping well.

The next case also shows an intolerance to larger doses than 0.000001 milligramme:

A young woman of twenty-one years with tuberculous laryngitis and some pulmonary involvement, who also had a history of slight anemia and of an episode of syncopation in 0.000001 milligramme of tuberculin by mouth on April 14th last without experiencing any reaction. Three days later she was given 0.000002 milligramme. She exhibited no symptoms attributable to the tuberculin, that day, but the following day suffered from another pleuritic pain, weakness, malaise, and nervousness. A dose of 0.000003 milligramme three days later caused similar symptoms on the day after the administration of tuberculin, with the addition of angioneurotic edema of the hands. Subsequent doses of 0.000001 milligramme produced slight reactions.

The following case describes a patient who was unable to take 0.000001 milligramme with safety:

A man of thirty-five years of age who had tuberculosis of one year's duration came to see me on March 15, 1913. The upper halves of both lungs were consolidated and covered with thickened pleura. The man had a rapid pulse and an evening temperature rise to 101° F. After three weeks of rest in bed, the patient was given tuberculin residue by mouth every five days. There was no reaction from the first dose of 0.000001 milligramme, and the next three doses of 0.000002 milligramme each or the following dose of 0.000003 milligramme. A subsequent dose of 0.000001 milligramme was followed by a severe reaction with fever.

Twenty cases among children at the Philadelphia Jewish Sanatorium for Consumptives at Eagleville, Pa., I shall report together. The ages varied from six to fourteen; the involvement from Class I to Class III of Turhan; the stage from incipient to far advanced of the National Association for the Study and Prevention of Tuberculosis; and the character of the lesion from quiescent to active. The patients had been under observation from several weeks to five months before tuberculin was given. The initial dose varied from 0.000001 to 0.0000001 milligramme to the initial 0.000001 milligramme. With the exception of anorexia in a few cases, and chest pains in one, there were no symptoms of a reaction. In
A CASE OF ACUTE DILATATION OF THE STOMACH COMPLICATING PNEUMONIA.

By Edward H. Goodman, M.D.

Philadelphia, Associate in Medicine, University of Pennsylvania.

We are indebted to Fussell (American Journal of the Medical Sciences, 1911, exii, p. 794) for calling attention to a hitherto little recognized serious complication of pneumonia, acute dilatation of the stomach. That the condition has been but little appreciated is evident, according to Fussell, from the failure to find mention of it in any textbook on medicine, and from the fact that up to 1911 only six cases had been reported in literature. He adds five from his own practice, a trenchant proof that it is by no means an uncommon complication.

Acute dilatation following operations is by no means a rare condition and is being met with frequently in surgical practice, but in pneumonia it seems to have been so infrequently encountered that reports of additional cases seems advisable. The following is the history of a case under my care:

Mrs. J. T., aged about sixty-three years, housewife. During the past two years patient had been subject to several attacks, which her physician, Dr. E. R. Mulford, of Burlington, New Jersey, pronounced undoubted appendicitis, namely, pain, tenderness, nausea, vomiting, with increase of temperature and pulse rate. The last attack was in December, 1912, although the patient stated she was never free from pain in the region of McBurney's point. She had always been very thin (best weight ninety-five pounds, now eighty-five), and had always had "indigestion." The physical examination was entirely negative, with the exception of tenderness over the appendicular region and spasm of the right rectus muscle on palpation. The pelvic examination was negative.

On February 27, 1913, an operation was performed by Dr. E. B. Hodge, of Philadelphia, and the appendix was found to be small and sclerotic, acutely flexed at about its middle; distal end larger than the proximal end. The abdominal visera were examined through the incision, and found to be normal, as was also the case with the pelvic viscera. Patient reacted from the operation very well, and on the following day, February 28th, apart from a low output of urine the general condition was most satisfactory.

*Read before the Section in Medicine, College of Physicians, Philadelphia, May, 1913.
March 3, 1913. Since the last observations patient had been doing very well, and is so far improved that she is allowed full diet. March 6th. Patient had a chill early this morning, and at 5 p.m. temperature was 104.6°F., pulse 106, and respiration 24. The abdominal wound was perfectly clean, with the exception of a small hematoma, on account of which one stitch was removed. Leucocytes 14,500. March 7th. I was called in consultation by Doctor Hodge on this date, and found the following condition: "Patient is breathing with difficulty, which is aggravated valvularally by a decided expansion on right side of chest; skin very hot and dry. Examination of the left lung is negative. Anteriorly over the right lung there is some impairment of resonance above and below the scapula. Above the right rib, along the anterior axillary line, there is marked dullness, with harsh breathing in the pectoral fold just under the breast. Over this area there are many sticky rales. Posteriorly over right lung, from midsagittal to base, the patient vomited at flat, and area of involvement there is bronchial breathing, bronchophony, whispered voice, and crepitant rales. Diagnosis: pneumonia, right side; lower and middle lobes."

March 8th. There were some friction fronds over the left pectoral region. Dullness over the right side has not increased in extent. Posteriorly, the consolidation with typical signs reaches to spine of the scapula. Left lung apparently normal. Leucocytes 17,000. March 9th. Over the right chest, about the mammary region, there is a decided expansion on rub. Posteriorly, dullness is marked to spine of scapula, at which place, breath sounds are harsh, but no rales are heard. Below spine of scapula there are bronchial breathing, egophony, whispered voice, and crepitant rales. At extreme base of right lung posteriorly the breath sounds are abnormal, vocal resonance very much decreased. To-day a well marked herpetic eruption appeared on the lips. The patient complained of a good deal of pain and recurrence was had while an ice bag was applied to the chest. Leucocytes 21,700. March 10th. Anteriorly, over the right side below clavicle to second rib, there is impairment of note with bronchial breathing. Posteriorly the signs are the same. Examination of left lung negative. Patient felt well comforted, though with complaints of considerable pain in the chest. Leucocytes 14,000.

March 13th. The temperature reached normal at 7 p.m. (ninth day of pneumonia). March 15th. Patient is much improved in very well general condition, and the pulse began to show the first signs of waning. The day was unseasonable in its heat and humidity, and the patient complained bitterly of the temperature. Skin is very moist and cool; perspiration free. Pulse is weak and irregular. The symptoms which were present on the 1st day have entirely disappeared, and the only abnormality is the occasional utilization of the urine, which has been scanty, or even absent. The patient's condition was very poor, with weak pulse and leacy skin, but after the lavage a decided improvement was noted. Strychnine, grain 1/20; and digitalin, grain 1/10, every four hours, and every three hours, and every three hours, and every three hours, and every three hours. Food was stopped by mouth, and nutritive enemas substituted: 800 c.c. normal salt solution were injected hypodermically and the lavage was repeated at 5 p.m., with a second hypodermoclysis of 1,400 c.c. of urine, which had been scanty, in quantity and reached 575° ounces.

March 17th. Food, in the form of albumen water, was begun to-day, as the patient now expelled the enemas, after having retained three. There has been no regurgitation and under the use of strychnine, digitalin, and caffeine the pulse has improved in quality and the blood pressure has become higher. March 18th. Patient's general condition is good. Has had a very comfortable day, and when one compares her condition to-day with that of three days previous, the recovery seems most noteworthy.

March 19th. The temperature, which has been normal, began to ascend to-day, with increased blood pressure, which was all the more surprising as digitalin had been discontinued and only 1/20 grain strychnine was being given three times a day. The amount of urine has become less. March 20th. Vision has become blurred, and patient cannot recognize her family; mental state dull. Leucocytes 25,350. Urine contains albumin and casts. March 21st. Patient comatose; convulsion of face, arms, and legs; edema of right side of face. Despite hot packs, salt solution, venesection, and purging, the renal condition became more aggravated, and the patient died.

That this case belongs to the class of acute dilatation of the stomach complicating pneumonia, and not to the class of cases in which, with a chronically dilated stomach, there is a sudden development of symptoms, is very evident. Doctor Hodge carefully inspected the abdominal cavity at the time of operation, and found the organs to be normal as far as could be determined; and a large, dilated stomach would have been most apparent had this been present. Although the patient had complained of gastric symptoms for some time, there was nothing in the appearance of the stomach at operation to suggest the nature of the trouble, and the symptoms referable to the stomach were supposed to be reflex from the appendix. The acute dilatation was not of the class designated as postoperative dilatation of the stomach, a condition unfortunately too common, and too frequently met with in surgical practice.

Mathieu (Archives des Maladies de l'appareil digestif, 1911, v. p. 490) has devoted a lengthy article to this surgical complication, which I reviewed in Progressie Medicine, December, 1912, p. 77. According to Mathieu, "in the majority of cases the distention began from one to three days after operation, although it may supervene during the operation, necessitating the discontinuance of the latter." Our patient complained of gastric symptoms for the first time on March 16, sixteen days after the operation; thereby, to my mind, ruling out the possibility of a postoperative dilatation.

Fussell, from the cases collected by him, has found that dilatation occurred before the crisis eight times, and after the crisis three times; and in the latter category belongs our case, where acute dilatation occurred on the eleventh day of the pneumococcus infection. Of the eleven patients, five recovered and six died, and this case must be put in the class of recoveries, as the cause of death was nephritis, and not the acute dilatation. The condition is a serious one, as Fussell estimated the mortality to be 55.5 per cent., but if our case is to be considered as one with favorable outcome, the proportion must be brought to fifty per cent. In surgical cases, Conner gives a death rate of 72.5 per cent., in 102 cases, and Laffer of 62.5 per cent., in 217 cases, and Fussell says, and rightly, that "this terrific death rate is probably largely the result of the true nature of the case being unrecognized."

A most interesting feature of this patient was the blood pressure estimation. During the course of the pneumococcus infection we were guided, as regards stimulation, very largely by the ratio of
blood pressure to pulse rate (Goodman, Therapeutic Gazette, July 15, 1911). This ratio in favor of blood pressure was fairly well preserved until the collapse incident to the acute dilatation was seen, when it fell to 95 mm. Hg. Stimulation at this time was most strenuous, and this, coupled with the immediate use of lavage and right sided decubitus, brought relief and caused a rise in pressure. On the 19th of March stimulation was markedly reduced, and the subsequent rise in pressure must be ascribed to the acute nephritis, leading to a pressure of 145 mm. Hg. and death.

Treatment. The success of treatment depends mainly on the prompt recognition of the condition, and the diagnosis is not at all difficult, if one bears in mind that acute dilatation of the stomach is a complication of pneumonia. The early signs are pain in the stomach, vomiting of blackish material, intense thirst, and distention of the abdomen. Later signs are, enormous distention of the stomach, increased gastric tympany, and subspissation splash. At first, the patient’s body is covered with a cold sweat, the expression is anxious, pulse small, running, irregular, and intermittent, and collapse extreme. The early passage of the stomach tube is the treatment par excellence. Fussell rightly says that “when a patient is collapsed, with running pulse, it is often feared that the passage of the stomach tube may be fatal; but the danger one runs from this procedure is insignificant compared with the danger the patient faces if lavage is not practised, and this is so readily accomplished and gives such prompt relief that its employment should not be debated.” Lavage should be continued until the return flow is clear, and the tube should be passed again at the first suspicion of returning dilatation.” After the lavage the patient should be placed on the right side, and even on the face, provided this does not hamper the breathing too much. No food or water should be given by mouth, and rectal feeding may be practised instead. Fussell recommends strychnine and eserine, which we employed in large doses, but without marked effect on the gastric condition.

As to the theories of acute dilatation of the stomach after operation, the aerophagia theory of Lardennois has received the support of Mathieu, and it is possible that this explains its occurrence in pneumonia. Mathieu says that the weight of the intestines can not cause enough traction to bring about constriction of the duodenum, for experimentally it takes a weight greater than that afforded by the mass of intestine, and he believes the gastric dilatation is primary and not secondary to other conditions.

Cases from the literature. An abstract of cases collected from the literature by Fussell is appended, together with abstracts of his cases.

Case III. Case reported by Herrick (Journal of the American Medical Association, March 31, 1906). E. S., aged thirty-six years. Admitted to the hospital with pneumonia. The right upper and lower lobes, and the left lower lobe were involved. The case proved to be an extremely severe one, and the patient’s temperature ranged from 101° to 104°. F.; the pulse from 115 to 130. After the patient had been in the hospital two days she was lectured upon: a careful physical examination was made and nothing unusual noted. On the fourth day of the disease, she was locked in death, and the patient’s recovery was expected. At 3 p.m. of that day, she vomited a large amount of dark brown fluid. At 6:30 p.m. she vomited, and at 7:15 she vomited again. In the evening she was delirious, vomited a large amount, abdomen greatly distended, but pneumonia was improved. The abdomen showed distention, and there were splashing sounds discovered. The stomach was washed out, the patient had peridical attacks of diarrhea afterward, but recovered.

Case IV. (Reported by Fussell, Thesis, Leipzig, 1904).—Case of peritonitis due to distension of the stomach. The patient was a female aged twenty-four years; admitted October 10, 1901; died October 16, 1902. Pneumonia of both lungs developed. On the evening of the 13th, while the pneumonia process was apparently improving, vomiting yellowish brown watery fluid. The urine was dark. The abdomen was markedly distended, and the patient was hypochondriac. Attempts were made to pass the stomach tube but failed. On the 15th the patient went into collapse and on the 15th died. Autopsy showed a monstrous dilatation of the stomach, together with dilatation of the duodenum and obstruction at the mesenteric point of the duodenum.

Case VI. (Weber, Transactions of the Clinical Society, London, xxxix, 1906.) Female, aged twenty-six years; ill with pneumonia, June 13, 1905. On observation June 15th, there was found great dilatation of the right upper lobe and also pericarditis. Suddenly, on June 17th, much abdominal distension; no pain, no vomiting. Stomach was washed; much black, greenish material obtained. Tympany did not at once disappear, but on June 20th, there was no tympany, and patient recovered.

Case VII. Fussell, i.c.) Mrs. B., aged seventy-six years. On October 18, 1904, the patient was suddenly seized with chill and fever, excreting pain on right side, and tenderness over the region of the bladder. October 19th, the temperature was about 102° F. Marked dullness over the lower lobe of the right lung. October 20th, there was dullness on the right side over the lower lobe of the lung, from the middle of the scapula to the right apex. There was many blowing sounds and pain and tenderness on the right side of the abdomen. The patient made a slow, but uninterrupted recovery from her pneumonia, though she was extremely weak. Suddenly, on November 5th, sixteen days after the initial chill, she vomited a large amount of undigested material; vomited several times that day. On November 6th, had great abdominal distension, and vomited material of decidedly fecal odor; was weak and collapsed. Distinct peristaltic waves may be seen over the region of a distended stomach. The gastric tympany extended far below the umbilicus. The stomach tube was passed, and forty-eight ounces of foul fecal smelling material removed. The stomach was then washed, and eight ounces of milk returned by the stomach tube. The washing was repeated every six hours until the afternoon of November 7th, when all vomiting ceased, and after passing many pitsals the patient entirely recovered.
Case VIII. (Fussell, l. c.) A young man, aged twenty years, was seized with a severe attack of pneumonia. The right lung was first involved, first the lower and then the middle lobe; his left lung then rapidly became involved, and finally he had apparently only his right upper lobe in use, though by that time there was some resolution at the right base. All this time, in the midst of the July heat of Philadelphia, the temperature of the patient was between 103° and 104° F. The pulse was extremely rapid, frequently reaching 104 a minute. Resolution began at the right base and slowly progressed, the patient's temperature dropped to normal by lysis. Suddenly, three days after the temperature had become normal, without warning he vomited a large amount of creamy, sour (not fecal) material. In a few hours there was great distention over the stomach itself. The left hypochondrium and the umbilical region were protuberant, while the right hypochondrium was flat. The complete outline of the stomach could be seen; tympany reached almost to the pelvis. The patient was collapsed, his pulse running. Notwithstanding his apparent moribund condition, a stomach tube was passed, a great amount of the same liquid removed, and the stomach washed. There was an immediate disappearance of the tumor, and the patient was much relieved. In six hours a second washing was performed, and all stomach symptoms disappeared.

Case IX. (Fussell, l. c.) H. B., aged thirty-five years. On January 28, 1911, was seized with pneumonia. On January 30th the lower left lobe was involved, and the disease remained restricted to that area of the lung. On January 31st he became extremely ill. There was a chill that rose to 102° F. and on February 2d there were symptoms of intestinal obstruction. The abdomen was greatly distended, and it was impossible to obtain a bowel movement by any means. February 3d, abdomen was still much distended; the patient was semicomatose. There were inches below the umbilicus, forming a tympanic tumor. Pulse rapid, but good. Complete consolidation of the lower left lobe, which was undergoing resolution. Patient was semicomatose. There was profuse vomiting. A stomach tube was introduced, and a small amount of sour material obtained, together with much gas. The epigastric tumor immediately disappeared, and the abdomen became flaccid. The next day, three successive times, distended abdomen was washed; bowel movements remained sluggish, but there was no return of distention of the stomach after the fourth washing. Eserine and strychnine were administered hypodermically.

Case X. (Fussell, l. c.) C. J., aged fifty-four years. Taken ill December 28, 1910, with a chill that was apparently influenza. Pulmonary consolidation rapidly developed, confined to the right base. March 4th, there was some abdominal distention, with vomiting of dark material; also retention of urine and obstinate constipation. The case had the appearance of an acute obstruction of the bowels. Suddenly, March 5th, the eighth day of the disease, in addition to distention, there was extreme abdominal pain, with collapse, as shown by rapid, running pulse, cold sweat, and a temperature of 98° F. There was marked consolidation of the right lower lobe of the lung, and an epigastric tumor extending apparently to the pubis. Great quantities (about two quarts) of foul, dark green material were washed from the stomach, with immediate relief of pain and disappearance of the abdominal distention; the bowels moving shortly after. The temperature rose to 103° F., and the man died of exhaustion fifteen hours after the stomach was evacuated.

Case XI. (Fussell, l. c.) Mrs. H., aged seventy-six years. Had a chill on April 16, 1911. Rapid complete consolidation of the right lung, with some consolidation at left base. Temperature ranged from 102° to 104° F. She was seriously ill, but did fairly well until the morning of April 20th, when she had a sudden collapse. Her pulse became running, her respiration very rapid, her abdomen greatly distended. On the early morning of April 21st she was in collapse, semiconscious, pulse 102, with great abdominal distention, more marked in the epigastrum. Gastric area apparently greatly distended, particularly to the left. The outline of the stomach could be plainly seen. There was marked peristalsis over the entire abdomen, and it was believed that the peristaltic sounds in the intestines could be distinguished from those of the stomach. No succussion splash could be brought out. Apparently she had great abdominal pain. There was no bowel movement for forty-eight hours. Notwithstanding the serious condition of the patient, lavage was instituted, and about a pint of foul fecal material was removed; after which salt solution introduced returned clear. There was apparently not very marked dilatation of the stomach, because while the stomach tumor itself disappeared after lavage, the general distention still remained, and this was evidently due to distention of the intestines themselves. The patient was relieved by the washing, but died about twelve hours afterward in collapse.

248 South Twenty-first Street.

CHRONIC INTESTINAL STASIS.

By L. Miller Kahn, M.D.,

New York.

Adjunct Attending Surgeon, Lebanon Hospital.

Through the efforts of a number of surgeons, the condition which is now known as chronic intestinal stasis has within the past few years received a great deal of attention at the hands of the medical profession. It will be the earnest endeavor of every thinking physician to estimate the value of these observations, and in carefully selected instances to offer to the patient whatever benefit may thus be derived.

It has been said that the present surgical activity in this field is an attempt on the part of the surgeon to take neurasthenia out of the head and put it in the abdomen. If that is to be the sole result, the surgeon himself is sure to have the greatest cause for lamentation. Many careful observers are united in thinking that there is a fairly well defined group of patients who suffer from chronic intestinal stasis, although there is as yet a lack of uniformity of opinion as to the causative factors.

There are primarily two groups of cases: One where the patients show symptoms in the abdomen, and refer all their trouble directly to the abdominal viscera; in the other the patients seem to be suffering from chronic intestinal poisoning, but the abdominal symptoms are usually of secondary importance. It will serve our purpose here to note that the first group and the second as well are variously held to result from visceroptosis, from a movable cecum, from membranous pericoltis, or from Lane's kink, and I will attempt to correlate these so that we may determine with greater clarity their pathological significance, acting either as separate entities or as combined forces to make for disturbed function.

ANATOMICAL AND PHYSIOLOGICAL BASIS.

A summary of some of the more important physiological facts will enable us to grasp the essential problems and to arrive at a basis for further conclusions, as all advances in this branch of intestinal surgery must be founded on a full understanding of the underlying physiology.

The stomach is supported in its position by its connection with the esophagus, above, by the gastrophrenic ligament, and on its lesser curvature by the frail gastro-hepatic omentum. The duodenum, the position of which is mainly retroperitoneal, is firmly held by its peritoneal covering, and its distal portion is fixed by the muscle of Treitz. The small

Read before the New York Physicians' Association, as part of a symposium on Chronic Intestinal Stasis, May 22, 1912.
Intestines are very loosely held by the mesentery. The ascending colon is maintained in position by the fusion of its peritoneum with the posterior abdominal wall and by the transverse mesocolon, which, in turn, supports the transverse colon; the splenic flexure of the colon is more firmly held in its high position by the fusion of its peritoneum with the posterior abdominal wall and by the gastrosplenic and costocolic ligaments. The descending colon is mainly retroperitoneal, due to the fusion of its peritoneum with the posterior abdominal wall down to the point of crossing the psoas muscle, where it has a free loop, the mesentery of which permits a wide range of motion. The retention of the abdominal viscera in their normal relations depends in great measure upon the maintenance of the intraabdominal pressure by the abdominal muscles, so that the integrity of these muscles must be unimpaired if the viscera are to be held in place. These supports are sufficient in the normal individual to fix the organs in position and maintain them. Complete development of these natural lines of support is effected when the complete cycle of visceral rotation and peritoneal fusion is accomplished.

The rate of passage of food through the intestinal tube is nicely adjusted to the chemical changes that take place, and this fine adjustment, if disturbed, is likely to lead to altered conditions, either in the food itself or in its rate of absorption. If the onward passage is hindered we have decomposition, with the formation of harmful products, and if too rapid, insufficient digestion and absorption (Cannon) (1). The natural lines of suspension of the gastrointestinal tract are so ordered that the onward movement of the contents is retarded only so long as to permit sufficient digestion and absorption, and there seems to be little doubt that with the loss of support from these natural lines of suspension the mechanism of digestion is interfered with. Whether such interference with digestion from this cause is sufficient to produce symptoms is the subject of our inquiry.

The best example of the interference with these supports is that which takes place when the splenic flexure of the colon is dragged down. From a survey of the function of the large intestine it seems clear that the splenic flexure is purposely hung high in order that the cecum and ascending colon—which are in effect a catch all for absorbable particles—may have a better opportunity of culling over the already digested food. Definite antiperistalsis has been demonstrated in morbid states in the large intestines, and perhaps in the normal as well, and it is believed that in the condition of cecum mobile, owing to a failure of fixation of the cecum, its movements are seriously and harmfully retarded, with resulting stasis of its contents. The ileocecal valve acts as a sphincter, as well as a simple valve, and distortion of the normal configuration of the parts, either by adventitious bands or dilatation of the cecum, may impair its functional integrity. The cecal sphincter serves to retain the intestinal contents in the ileum until sufficient digestion has taken place before permitting the chyme to enter the cecum. (Hertz) (2). Tracings made with the aid of the x rays reveal the fact that the large intestine below the splenic flexure is emptied in a single act, and that thereafter during the next twenty-four hours waste material accumulates in the distal colon. As it collects in the descending colon it first halts at the junction between the pelvic colon and the rectum, where an acute angle offers some obstruction to progress. On becoming distended, the pelvic colon rises and widens its acute angle with the rectum, thus removing the obstruction to the advancement of fecal matter. (Cannon) (1). Interference with this simple mechanical device, either by faulty position of the colon due to prolapse or by hindering bands (Lane’s last kink), may be responsible for stasis in the large intestine. Following any disturbances of the onward movement of the gastrointestinal contents, the noxious products of faulty digestion are absorbed, and in their wake may come the symptom complex which we are seeking to identify.

In the review of the physiological factors entering into our problem we must not forget that the act of defecation depends in great measure on the abdominal musculature, and that with the loss of tone of these muscles evacuation of the bowels becomes difficult. Here, then, are the generally accepted group of physiological facts upon which any treatment is to be based.

MECHANICAL FACTORS PRODUCING STASIS.

It now becomes necessary to identify the mechanical hindrances to the normal trend of the gastrointestinal contents, and, having identified them, to ascertain, if possible, their etiology, in order that the proper corrective measures may be applied.

The question to be answered is, Are we dealing with a pathological condition arising from some intraintestinal affection, or is the whole picture that of a departure from the normal due to defective or abnormal development? Among the number of conditions which are held to be responsible for chronic intestinal stasis of varying degrees we have Jackson’s membranes or veils, Lane’s kink, the movable cecum, various angulations of the gastrointestinal tract, general visceroptosis, and movable kidney.

Jackson’s membrane, which extends from the lateral abdominal wall and fuses with the visceral peritoneum of the ascending colon and cecum, has many variations. It may or may not include the cecum, and it may enclose the transverse colon and fold it parallel to the ascending colon, thus producing the “double barrelled colon.” Sometimes the ascending colon and cecum are enclosed within it as if in a tight bag. It is most likely that the occasional band seen at the hepatic flexure of the colon or that extending to the gallbladder results from the same causes which produce Jackson’s membrane.

Lane’s kink, binding down the last four or five inches of the ileum, is seen distorting the normal contour of the gut and certainly operating to restrict its movements. Iliac stasis may not only be produced by Lane’s kink, but may also be secondary to colonic stasis or to an appendix so placed that the passage of the iliac contents into the cecum is obstructed. The train of events fol-
ollowing iliac stasis is as follows: The band which supports the last four or five inches of the ileum is dragged upon, and the proximal ileum and perhaps the cecum prolapse, producing a sharp kink at this point. The jejunum is also pulled down in a straight line, and produces a sharp angle with the lowest portion of the duodenum at the duodeno-jejunum junction, thus producing a distended duodenum. According to Jordan (3) we have, as a result, ulceration of the duodenum, cholecystitis, and chronic pancreatitis, which, he says, are regularly found in operation on the subjects of intestinal stasis.

In the condition described as cecum mobile, and on which Wilms has laid such great stress, the cecum is freely movable and unable to empty itself with sufficient rapidity. It becomes dilated, hangs over the pelvis, causes local symptoms, to be described later, and perhaps is responsible for some of the graver constitutional manifestations of chronic intestinal stasis. Wandel found, in 640 autopsies, sixty-six instances in which the cecum was sufficiently movable to permit kinking, torsion, and displacement. Wilms contends that the abnormal mobility of the cecum interferes with its dynamics and leads to a definite symptom complex.

When attention was first called to the rôle played by adventitious membranes and bands it was thought their presence was to be explained entirely on the basis of an inflammatory reaction of the peritoneum to intraintestinal changes, and that they were identical with the adhesions one sees after trauma or infection of the peritoneum. A more careful investigation of these membranes, and of the cecum mobile as well, combined with a study of the embryological development of the peritoneum has shown, conclusively, I think, that in the main we are dealing with a morphological development or a failure on the part of the fetal structures to complete their full ontogeny. The allied slipping of the right kidney is almost always due to a failure of the colon to rotate over the anterior surface of the kidney, and with failure of fusion of the peritoneum of the colon with the abdominal wall, there is insufficient support for the kidney. The proof of the embryonic origin of the bands and membranes or veils is based on the following: Flint (4). Eastman, and others have found these veils and bands in very young infants and in embryos. Eastmann (5) has forcibly brought out the resemblance of Jackson’s membrane and Lane’s kink to the fetal peritoneal fold described by Jonnesco and Jivara, and designated by them the parietocolic fold, and to the bloodless fold of Treves. Careful dissections revealed this bloodless fold in nine out of twenty-eight fetuses. Whatever the origin of these folds (parietocolic) in the fetus, there will be no doubt in the mind of anyone who will examine the region of the cecum in a few fetuses that they exist before birth, and it has been found that they are readily demonstrable in one form or another in approximately twenty per cent. of fetuses after the sixth month. The bloodless fold of Treves was present in a larger proportion. Careful microscopical examinations of these membranes have not shown them to be of inflammatory origin. Lane has explained their presence as evolutionary, not inflammatory, and that they exist in the first instance for the advantage of the individual.

It will be recalled that the ileocecal junction migrates in its early course from below upward and to the right, crosses the abdomen, turns downward under the right lobe of the liver (hepatic flexure), and then continues downward until it completes its rotation, and the cecum finally finds lodgment in the right iliac fossa. The chief developmental defects which may take place are, failure on the part of the colon to descend from its high position under the liver, failure of its peritoneal coat to fuse over the right kidney (failure of rotation), and finally failure of the peritoneal coat of the colon to fuse with the parietal peritoneum at its lowest position, thus producing cecum mobile. In the course of its migration through the peritoneum (Mayo calls it burrowing), the ascending colon unquestionably picks up these additional bands and veils. It has been suggested that these membranes are due to “a more extensive fusion of the great omentum to the colon, which is dragged down with the descent of the cecum, or that they simply represent a more marked attachment of the large intestine to the abdominal wall.”

These morphological studies would lead one to the conclusion that movable kidney, the cecum mobile, and the prolapsed transverse colon are in the main due to a failure of fusion of the visceral with the parietal peritoneum in the normal manner, and that Lane’s kink is either due to increased mobility of the cecum or that, like Jackson’s membrane, it is a fetal anomaly. That acute or chronic inflammation may be superimposed upon any of these conditions is readily conceivable, and this is likely to result where any of these prenatal defects interfere with the normal activity of the parts.

It is not intended here to obscure the fact that adhesions do occur in the course of infections of the peritoneum, but simply to point out that these infections have not been sufficiently shown in the cases of Jackson’s membrane or Lane’s kink. It will now be seen that with deficient rotation of the colon, and failure of fusion of its peritoneum with the abdominal wall, we may, and indeed, often do, have in the same individual prolapse of the stomach from dragging down by the transverse colon, movable kidney, cecum mobile, and any of the various bands. It is the opinion of the writer that all of these conditions are simply degrees of the same general type of congenital abnormality.

SYMPTOMS.

It must from the first be fully admitted that we may have any or perhaps all of the before mentioned anatomical variations present, without symptoms of any kind. I have frequently seen Jackson’s membrane or a movable cecum, for example, in patients operated upon for other conditions and in whom, I am certain, they were producing no symptoms. In dealing with the symptomatology of Jackson’s membranes, Lane’s kink, and cecum mobile we are in the midst of much confusion, for it is only fair to say that the symptoms noted by one observer as due, let us say, to Lane’s kink have with equal positivity been asserted by another to be the result of Jackson’s membrane. And as usual the truth lies somewhere between.
The local symptoms, as found in the right iliac fossa and right side generally, are a sense of dull ache without tenderness and with frequent attacks of severe pain, sometimes referred to the umbilicus. These symptoms are always accompanied by constipation. In many of these cases the symptoms are gastric with eructation of gas and distention. The gastric disturbances are unrelated to the time of food taking. The bowels move only with catharsis. The cases may be confounded with chronic or interval appendicitis, and, indeed, nearly always are. There may be attacks of colic which would suggest an early case of obstruction. These attacks are almost always afebrile, and there is usually no muscular rigidity over the affected area. Wilms finds in the cases of cecum mobile that there is a distinct fullness in the right iliac fossa, as if one were palpating an air cushion in the region of the cecum. There is often tenderness over the entire right side of the abdomen—not localized, as in appendicitis. These symptoms, along with general weakness and the general desire to lie down (which affords more or less complete relief), seem to characterize the group, whether caused by a Lane's kink, Jackson's membrane, or a cecum mobile. Rovsing attaches special importance to the relief of symptoms by rest in bed as diagnostic of visceroptosis. In gastrocolposis there is persistent constipation, weariness, headache, loathing of food, and, later, cardialgia to the left of the median line. The quality of the food, says Rovsing, has no significance so far as the pain is concerned, whereas the quantity, the weight, and the mass of the food are of great importance; for which reason these patients can get along only by taking many quite small meals during the twenty-four hours (6).

The constitutional symptoms of chronic intestinal stasis, according to Lane, are, loss of fat, circulatory changes with cold and livid hands and feet, diaphragmatic respiration, pigmentation of the skin, muscular pains and weakness, headache, failure of the resisting power of the patients, rendering them directly liable to tuberculosis, gout, rheumatoid arthritis, and, in the female, degeneration of the mammary glands. He also intimates very strongly that thyroid disease results directly from chronic intestinal stasis. Lane has a very advanced pupil in Barrington-Ward (7), who believes that not only is tuberculosis an end result of intestinal stasis, but that infection of the urinary tract is invariably the result of such stasis.

In the correct diagnosis of chronic intestinal stasis the surgeon must depend greatly on the roentgenologist, whose activity in this field has added so much to our knowledge of the subject; but it may also be said the roentgenologist should follow the cases to the operating table in order that he may see to what extent the operative findings bear out the earlier diagnosis. In the X-ray diagnosis of intestinal stasis something more than radiograms is required, and even in the hands of the most expert the interpretations will differ. Often to clear up a case a large series of plates taken at intervals is necessary, and even then operation should be advised only on the combined symptoms and the X-ray findings. Hasty and incompetent work will only bring discredit to both the roentgenologist and the surgeon. In the diagnosis of questionable cases it must not be forgotten that ulcer of the stomach and duodenum may give symptoms which might lead to confusion, and the real condition be overlooked in our search for the cause of the stasis lower down in the digestive tract. Jordan (3) holds that the occurrence of duodenal distention, as seen by the X-ray, is so constant that he has come to regard it as positive for intestinal stasis, and that in the absence of duodenal distention he would hesitate to make the diagnosis of stasis.

**Surgical Treatment.**

In those cases where after a careful diagnosis has been made, and the most efficacious medical measures tried and found wanting, the surgeon has attempted to solve the problem with a fair measure of success. Believing that in gastrocolposis we have the chief source of the symptoms, Rovsing (6) fixes the stomach to the anterior abdominal wall, at the same time shortening the gastrocolic ligament. Coffey (8), with much the same end in view, fixes the great omentum and the transverse colon to the anterior abdominal wall; thus producing a hammock in which the stomach is supported. Lane and his followers, identifying the constitutional symptoms as due mainly to intestinal stasis, are sure that the remedy is the short circuiting of the iliac contents as directly into the rectum as possible, and with this in view divide the ileum at its entrance into the cecum and implant the proximal end of the ileum into the lowest accessible portion of the descending colon. This in a measure excludes the large intestines; but, owing to the reverse peristalsis in the colon under morbid conditions, the entire colon may show a tendency to fill up after this operation. Lane at first advised colectomy for these cases, but latterly, with the improved technic for ileocolostomy, colectomy has been practically abandoned.

In the cases where the movable cecum is responsible for either the stasis or the purely local symptoms Wilms strongly advocates the fixation of the cecum, and plication of the cecum for chronic distention has been successfully done. Great relief has followed the division of Lane's kink where the ileum was bound down, producing distress of the subacute type. Jackson (9) and others have reported relief of the chronic stasis, and the local symptoms following division of the membranes and freeing the colon and cecum from confining bands; but there is a marked tendency toward reformation of the adhesions when these veils are divided, with recurrence of the symptoms.

**Retrospect.**

I have purposely brought these measures together to call attention to the fact that we are facing a new phase of surgery of the abdomen—reconstructive surgery; and at present the problem is undergoing its evolution. It should be said in closing that no patient should be subjected to operation until a satisfactory diagnosis has been arrived at, and that no operation be done on incomplete evidence. While the successes in the surgery of intestinal stasis have been numerous, it is likely that the failures have not been reported with the same
Polycythemia; with Report of a Case in an Insane Patient.

By Robert M. Alexander, M. D.

Wernersville, Pa.

Case. E. C., aged sixty-five years, was admitted to the Wernersville State Asylum in 1894. For many years patient has had a florid complexion, but was able to work during that time. Uses tobacco in moderation; appetite good; complains at times of dizziness.

Laboratory findings: Patient is a rather poorly developed adult male. There is no palpable enlargement of superficial lymph glands. The pulse is slightly increased in rapidity, and compressible; the superficial arteries roll beneath the fingers when palpated. The face is apparently flushed, but upon close inspection a violaceous or bluish tinge is seen, which is most apparent upon the lips. The pupils are equal and react to light and accommodation; there is a pterygium on each eye, involving the cornea; the conjunctivae are somewhat injected. The tonsils are small and congested; the pharynx injected and coated with mucus. The tongue protrudes in the median line, is slightly coated, and tremulous. Thyroid gland appears normal.

Chest—Inspection: Expansion limited, but equal on the two sides. The skin appears normal in color, but, after percussing, the veins stand out and it becomes bluish in color. There is retraction in the supraventricular fossae, and the infraclavicular fossae are deepened. An impulse is visible beneath the xiphoid cartilage synchronous with the heart beat. Palpation: Prematurity appears normal; apex beat is felt in the fifth interspace, 3 1/2 inches to the left of the sternum. Percussion: The percussion note is slightly overresonant; cardiac area normal in outline. Auscultation: Breath sounds slightly exaggerated; heart sounds of fairly good quality; a slight accentuation of the second sound: no murmurs heard.

Abdomen: The liver extends to the costal margin; gallbladder and kidneys not palpable. The spleen shows no enlargement. No areas of tenderness, and no evidence of fluid in the peritoneal sac.

Extremities show dilatation of superficial veins, but no other unusual phenomena.

Laboratory findings: Urine shows a cloud of albumin and the presence of leucocytes and many hyaline casts. Blood pressure is 180 mm. Hg; hemoglobin 110 per cent.

Examination of the blood shows the erythrocyte count to be 6,275,000. The highest count made was almost 7,000,000. The erythrocytes are somewhat increased in size and have a bluish tinge. White blood corpuscles were few, and the differential count showed 57 per cent. polymorphonuclear leucocytes, 20 per cent. lymphocytes, and 1 per cent. eosinophiles.

Polycythemia occurs as a secondary condition in great altitudes. Laquer in the Arch. für klinische Medizin, April 19, 1913, reported a study of his own blood. He went from a low altitude to an altitude of 9,000 feet, where he remained for four weeks. Both the red blood count and the hemoglobin began to rise slowly during the second week, and on the fourteenth day reached their maximum; the red cells having increased fifteen per cent. and the hemoglobin sixteen per cent. After his return to the lowland the red cells decreased suddenly, and the hemoglobin, gradually, to their original proportions. Six dogs were bled until about half the volume of blood was removed, and they were then taken to the 9,000 foot altitude. The restoration of the normal blood volume required sixteen days, while six dogs kept at a lower level required for this twenty-seven days, or seventy per cent. more. He is inclined to ascribe the blood regenerating power to the low oxygen pressure. Cohnheim and Weber in the Archiv of the same date state that in order to determine whether or not there is an actual increase in blood corpuscles at high level, they examined repeatedly the blood of twenty-three men who had worked for twenty-three years on the Jungfrau railroad, at an altitude of from 9,000 to 11,000 feet. Both red cell count and hemoglobin were decidedly increased over the normal for healthy men at lower levels. Osler states that the excessive globulism of great altitude is compensatory to lack of oxygen in the air, and that there is an increased activity of the bone marrow; which activity is present in erythrocythemia proper, and the disease is regarded as a primary lesion of the erythroblastic tissues of the bone marrow, just as leukemia is an affection of the leucoblastic elements. There is also an increased viscosity of the blood which favors the stasis and capillary engorgement.

Other causes of erythrocythemia are emphysema and congenital heart disease. In a few cases polycythemia has been found related to tuberculosis of the spleen.

The three clinical features in erythrocythemia proper are a change in the appearance of the patient, enlargement of the spleen, and excessive globulism. The superficial bloodvessels, capillaries, and veins look full, so that the skin is always congested; in warm weather being of a brick red color, in cold weather cyanosed. The engorgement of the face may be extreme, extending to the conjunctivae. In the cold the cyanosis of the face and hands may be as marked as any that is ever observed. There is also often a remarkable vasomotor instability, the hands becoming deeply engorged when held down and rapidly anemic when held up.

N. E. Brill, in the Medical Record for April 8, 1911, reports a case which, in addition to an erythrocytosis of between 8,000,000 and 10,000,000 cells, and a leucocytosis varying between 20,000 and 45,000 leucocytes, presented few features of a cyanosis. A much relatively diminished hemoglobin content, the color index being below 1, showed marked signs of bone marrow involvement, with a colossal spleen and a very large liver.

The spleen, Osler states, is usually enlarged, but not to the great extent met with in leukemia. It may vary in size from time to time. It is hard, firm, and painless. The total bulk of blood is enormously increased, and the ratio of corpuscles to plasma is high. The polycythemia ranges from

Patient exhibited and paper read before Berks County Medical Society, June 10, 1913.
UNILATERAL SEPTIC INFECTION OF THE KIDNEY.*

By A. P. CONDON, M. D.

Omaha, Nebr.

By unilateral septic infection of the kidney is meant its invasion by virulent microorganisms and their products, usually producing within it numerous miliary abscesses, which may or may not coalesce, and often accompanied by such violent general symptoms that, without the removal or drainage of the affected organ, death usually ensues.

This form of infection was classed by the older writers with the other kinds of acute supplicative renal infections, under the term surgical kidney. No attempt was made to treat it as a distinct entity until within the last few years, when a number of these cases have been reported. The best articles have been written by Brewer and Cobb, the former making a series of animal experiments, which proved the possibility of a unilateral hemato-
genous infection. I have had two cases of uni-
lateral septic infection of the kidney, the histories of which I will give briefly:

Case I. Mrs C, aged twenty years, entered the Nicholas Society Hospital March 15, 1912. Twenty-four hours before admission she was seized with pain in the right kidney region. She had a severe chill, vomited several times, and the temperature reached 103° F. She had previously been in good health, and there was no history of an injury. In 1910, I operated upon her for appendicitis. She made a good recovery. The record showed that the uranalysis at that time was negative. The physical examination of the patient at the hospital showed her to be five months pregnant. The abdomen was tense all over, there was some tenderness over the right side of abdomen. There was marked tenderness over the kidney and rigidity of the lumbar muscles and also the muscles of the right side of the abdomen. Temperature, 104° F.; pulse, 130; leucocytes, 24,000, eighty-four per cent polymorphonuclear. The patient was semidelirious and was apparently in a very toxic condition. Examination of the urine showed a moderate pyuria, microscopic blood, albumin, 0.6 per cent, and a few granular casts. As to the urinary findings previous to her entering the hospital, I do not know. Ureteral catheter-

Case II. Mrs R, admitted to the hospital March 24, 1909. Aged twenty-eight years, a slightly built woman, had always had good health. One child, six years old. No miscarriages; menstruation normal. Family history negative; no history of injury. Eight months previous to admission she noted the patient did not sleep well. The abdomen was somewhat larger than the left. For four months this side had increased in size. She had had pain in the abdomen and back, and also difficulty in retaining her urine. The abdomen was enlarged to the size of a first months' pregnancy. Physical examination showed an ovarian cyst on the right side. On March 25th, an operation was done; the cyst was removed and an adherent appendix. The urinar.

*Read before the Nebraska State Medical Society, May 15, 1913.
localized tenderness over the kidney. I decided on May 4th to make an exploratory operation, and then removed the kidney, which was increased to twice its normal size. There was a moderate degree of inflammation in the pelvis, but no retention. On section, the kidney tissue showed a number of small abscesses disseminated throughout its substance. The patient made a complete recovery, and has never since had any renal trouble.

The first case belongs to that fulminating type of infection which demands early and radical operative treatment. I am convinced that this patient would have died had she not been operated upon, though possibly not so soon. I believe that if she had been operated upon during the first twenty-four hours after the beginning of her trouble, she would have lived. It was one of those cases, like some of appendicitis and of acute osteomyelitis, of the most virulent intoxication, in which time is so important an element.

The second case illustrates that type in which the infection is milder. Just what the final outcome would have been without an operation we cannot say. I believe, however, her symptoms would have gone on, gradually growing worse, the abscesses in the kidney coalescing and destroying it, unless death came sooner from sepsis.

This form of kidney infection is hematogenous in origin, occurring usually in persons apparently in normal health. Women are more likely to be attacked than men, as pregnancy predisposes them. The increased congestion of the kidney, on account of the pressure on the renal vessels by the gravid uterus, is no doubt a cause. The right kidney is more often affected than the left, the reason for which I believe is that it is more often displaced, and therefore more liable to passive congestion. This also explains the unilateral involvement. It may arise during the course of some other infection in the body, such as erysipelas, endocarditis, influenza, scarlet fever, typhoid fever, pneumonia, and osteomyelitis. In fact, in any infectious process the organisms may be secondarily deposited in the kidney. This form of renal infection is distinct from that class of renal abscesses due to an ascending infection.

Some of the acknowledged authorities in renal diseases, among them Guyon and Albarran, are of the opinion that many of the kidney infections, secondary to bladder troubles, are also hematogenous in origin. The kidney is the most vascular organ in the body. Landergren has observed that, under the action of strong diuretics, the amount of blood which passes through the kidney in a minute’s time equals its weight. On account of its extreme vascularity, a passive congestion is easily produced, and this is the most frequent predisposing cause of infection. Normally the kidney excretes various microorganisms without injury to its substance. It is not unusual to find the colon bacillus, and in typhoid fever and tuberculosis the organisms causing these diseases are often thrown off in the urine without any involvement of the kidney structure. The organisms causing this form of infection belong to the pus organisms, and the most frequent is the colon bacillus. I am convinced that we never have an infection in the kidney without some previous change in the renal circulation or a physiological or pathological disturbance in the kidney itself. These changes may be so slight that the patient’s attention may never have been directed to the kidney, but are sufficient to cause a lowered resistance in the organ, and thus give rise to a suitable soil for infection.

The symptoms of unilateral septic infection of the kidney appear suddenly. There is pain over the affected organ, extending around the upper part of the abdomen, and this is severe and continuous. It is that kind of pain described as intrarenal, in contradistinction to extrarenal pain or colic, which is intermittent or paroxysmal and produced by changes in the ureter or pelvis. The pain of septic infection appears sometimes so suddenly and is so intense that the condition has been mistaken for a visceral perforation or fulminating appendicitis. In this form of infection there is always marked tenderness over the kidney, and this is so apparent that the slightest pressure is complained of, and it is greatly intensified by fist percussion. The point of greatest tenderness is at the costovertebral angle. There is hyperesthesia of the skin over the kidney and rigidity of the lumbar muscles. There is usually vomiting, fever, rapid pulse, prostration, and a high leukocytosis. The fever is continuous and of a typhoid character. There are usually chills and sweating. The patient affected with this malady impresses one as being very ill.

The urinary findings vary; in fact, pathological findings may be absent. There is, however, usually some pus, albumin, and microscopic blood. In two of Cobb’s seven cases the urinary findings were negative. One would naturally expect, with such marked general symptoms, to find a great deal of disturbance in the renal secretion, but this is not the case. The finding of pus, blood, and albumin aids one in the diagnosis, but their absence should not deter us from making this diagnosis if the general symptoms point to a kidney infection. A cystoscopic examination, together with ureteral catheterism, should be made. If there are albumin and pus, one will be able to tell from which kidney it comes, and also to determine the presence of the other kidney and its functional capacity.

To differentiate this form of renal infection from acute abdominal conditions with similar symptoms is not always an easy matter. The suddenness of onset without a previous history of urinary trouble, the location and kind of pain, the great prostration, chills, high temperature, extreme tenderness over the affected organ, together with the urinary findings, will determine the differential diagnosis.

In regard to the indications for operation I would say, that one should be governed entirely by the intensity and progressiveness of the symptoms. If the infection is of the fulminating type, attended by severe pain with marked tenderness, high temperature, and a polymorphonuclear leucocyte count among the eighties, such a patient should be operated upon at once, just as one should operate on an acute osteomyelitis or any other infection showing the fulminating type of septic intoxication. On the other hand, if the symptoms are milder, pain less severe, temperature ranging from 100° to 103° F., a relatively low polymorphonuclear count, the general toxic symptoms not great and not progressing in severity, such a patient may be watched, and if the symptoms remain stationary or decrease,
operation may be deferred. Some of these cases will no doubt undergo resolution, and recovery will take place without operation. As to whether the kidney, when operated upon, should be drained or removed depends on the condition found. A kidney which is the seat of miliary abscesses will be recognized by inspection. It is enlarged, mottled, tense, filled with blood, and if there has been sufficient time for their development there will be observed numerous small yellowish and blackish areas, which on stripping the capsule are seen to jut out from the cortex. Such a kidney should be removed. If there are no abscesses, but simply a large, tense, hyperemic kidney, splitting the capsule or draining may relieve the symptoms.

City National Bank Building.

Prize Essays.

Questions for discussion in this department are announced at frequent intervals. So far as they have been decided upon, the further questions are as follows:

CXXXVI.—How do you treat cholera infantum? (Closed July 15th.)

CXXXVII.—How do you treat threatened abortion? (Answers due not later than August 15th.)

CXXXVIII.—How do you treat insomnia? (Answers due not later than September 15th.)

CXXXIX.—How do you treat chancre? (Answers due not later than October 15th.)

Whoever answers one of these questions in the manner most satisfactory to the editor and his advisers will receive a prize of $25. No importance whatever will be attached to literary style, but the award will be based solely on the value of the substance of the answer. It is requested (but not required) that the answers be short, if practicable, no one answer to contain more than six hundred words; and our friends are urged to write on one side of the paper only.

All persons will be entitled to compete for the prize whether subscribers or not. This prize will not be awarded to any one person more than once within one year. Every answer must be accompanied by the writer's full name and address, both of which we must be at liberty to publish. All papers contributed become the property of the Journal. Our readers are asked to suggest topics for discussion.

The prize of $25 for the best essay submitted in answer to Question CXXXI was awarded to Dr. Joseph V. Klauder, of Philadelphia, whose article appeared on page 233.

PRIZE QUESTION CXXXV.

THE TREATMENT OF BURNS.

(Continued from page 237.)

Dr. Rose A. Bowers, of Michigan City, Ind., observes that:

When the body is subjected to intense heat or to the action of caustic chemicals, as strong alkalies or corrosive acids, certain physical and chemical changes take place in the tissues; according to their degree of severity, three degrees of burns are classified.

A burn of the first degree is one where there is merely a hyperemia or redness of the skin, produced by the transient exposure to heat slightly less than 212° F., or to the temporary action of caustic alkalies or acids. When two thirds of the surface of the body is involved in a first degree burn, death usually results.

Burns of the second degree are those in which the deep layers of the skin are involved; owing to the oxidation of serous fluid watery blisters are formed. If one third of the body is involved in a second degree burn the results are usually fatal.

Burns of the third degree are those which not only affect all the layers of the skin, but which include the muscles, bloodvessels, nerves, and bony structures, as a secondary result of the damage done to tissues—sarcologic acid and poisonous albuminous substances are produced which act as a toxin. Necrosis and gangrene are frequent, because the parts involved are deprived of their blood supply and nourishment.

Burns of the first degree may be treated by applying a two per cent. solution of picric acid to the affected parts, or the burned surface may be dusted with equal parts of zinc oxide, boric oxide, and powdered starch, followed by the application of a loose, soft bandage; lead and opium water have been frequently applied with gratifying results. In the absence of other remedies sterilized water may be used. When the pain cannot be controlled otherwise, the hypodermic use of morphine is indicated.

In burns of the second degree we should relieve the shock and pain, if necessary, by one quarter grain of morphine. The next effort will be one to prevent infection. The blebs should be emptied when they are full of serum; this may be done by puncturing the bleb at its edge just through the healthy skin, allowing the epithelium to remain as a covering. After carefully cleansing the healthy tissues about the burn, the burned area should be irrigated with normal salt solution and gently mopped with soft gauze to remove foreign matter.

Anesthesia may sometimes be necessary to thoroughly cleanse a burned surface. There should next be applied a dress-sing which is both antiseptic and analgesic. Various solutions and emollients have been suggested and employed, but none as yet has been found to be the ideal. Picric acid may be applied in one to two per cent. solutions; a serviceable solution may be made by dissolving seventy-five grains of picric acid in a pint and a half of water, to which is added two ounces of alcohol. This should be applied to the cleansed burned surface by placing strips of sterile gauze wet with this solution; these are covered with absorbent cotton and bandage. The dressing should be changed in about four days. Equal parts of hydrasul wool fat and zinc oxide ointment may be applied to the burned surfaces and covered over with sterile gauze and soft bandages. Ointments of boric acid or ichthiol have been found advantageous.

In the burns of the third degree the shock and pain should be allayed by a quarter grain dose of morphine and in some cases a permanent warm bath may be employed. If a limb is so involved that the possibilities of nourishment are destroyed, amputation of the limb should be resorted to, as soon as the symptoms of shock have sub-sided. Saline and boric acid solutions should be used to cleanse the burns of the third degree. Stronger antiseptic solutions are dangerous because of the possibility of absorption. Simple sterile dressings should be applied. Dressings should be less frequent than as the degree of infection in each individual case demands. Ulcers should be touched with a
two per cent. solution of nitrate of silver, and the
sloughs should be removed when it is possible to
do so. Skin grafting may be employed in those
cases where it is indicated.

The adjuvants to the local treatment must 'al-
ways be borne in mind; the pain, collapse, restless-
ness, and heart failure must all receive appropriate
treatment.

G. J. Ellis, of Covington, Ky., writes:

Our choice of local applications for burns is
determined by their severity and extent, but in all
cases the principles are the same; protection and
antisepsis with as infrequent changing of dressings
as possible. For a burn of a few square inches in
extent, not beyond the degree of vesication, we
may use an ointment of five per cent. boric acid in
petrolatum, to which one per cent. of cocaine may
be added for the first day or two. For a larger burn
of the same degree, the best application is picric
acid, which is most conveniently prescribed in six
per cent. alcoholic solution; three ounces of this
solution to be added to one quart of water. Strips
of gauze saturated with this solution are applied,
covered with cotton, and lightly bandaged. This
dressing may be left undisturbed for three or four
days, and a second similar dressing will often be
sufficient to complete healing. As vesicles form,
they should be punctured and drained, allowing the
skin to settle on the underlying surface as a pro-
tection. The utmost care should be exercised in
changing the dressings, as well as in removing over-
lying clothing when the patient is first seen, all
adherent fabric being removed by prolonged soaking
with warm normal saline or two per cent. boric
acid solution. In treating large burns, the dress-
ings should be removed and replaced in small sec-
tions to avoid chilling. Deeper burns should be
be treated with a five per cent. boric acid ointment, or,
in the case of an extremity, in a continuous bath of
warm one to two per cent. boric acid solution.
Hemorrhage may be serious during sloughing, and
is best treated by compression. After sloughing
the treatment is that of any other granulating
wound; stimulating applications, solid stick of
nitrate of silver for exuberant granulations, and skin
grafting. One drachm of balsam of Peru to two
ounces of castor oil, ten per cent. thymol iodide
ointment, and from five to ten per cent. scarlet red
ointment are excellent applications. Destruction of
the entire thickness of the skin will always be fol-
lowed by cicatricial contraction, which may be
lessened by skin grafting and the use of splints and
extension. Anulation may be required in severe
burns of the extremities. Burns of the conjunc-
tiva and cornea are treated by cocaine instillations
and cold compresses to the eyelids, keeping the
pupil dilated with atropine and frequently separ-
ating the conjunctival surfaces and instilling castor
oil to prevent adhesions. Flame and steam are
sometimes inhaled, causing burns of the fauces and
upper respiratory pas-sages—a very dangerous
condition often leading to edema of the glottis.
These patients should be kept in a warm, moist at-
mosphere, alkaline antiseptic sprays and gargles
employed, and tracheotomy or intubation per-
formed on the approach of dyspnea.

General treatment is required for the pain and
initial shock as well as for the complications. Pain
should be relieved by the hypodermic use of mor-
phine; in severe burns it is often necessary to ad-
minister morphine before examining the patient.
Shock is combated by stimulants (strychnine and
alcohol) and warmth. Besides the common wound
infections, which need not be considered here.
burns are especially liable to produce internal con-
gestions. Cerebral congest-ion, indicated by rest-
lessness, headache, and often delirium, is treated
by the application of an ice cap and the administra-
tion of bromides. Pulmonary congestion causes
pneumonia and pleurisy, which are treated by the
usual methods. Intestinal congestions are probably
the most frequent internal complications of burns,
often leading to duodenal ulcer. Diet should be
entirely fluid, bowels moved by enemas and salines
when required, and any diarrhea immediately
checked with opium. If duodenal ulcer is suspect-
ed, feeding should be exclusively per rectum, and
bismuth in large doses should be given. Iron,
quinine, and strychnine are useful during con-
valescence. After recovery plastic surgery may be
necessary to correct deformity resulting from cic-
atricial contraction.

Dr. Nelson Du Val Brecht, of Washington, D. C.,
states:

The therapy of burns may be considered under
four headings: First, prophylactic; second, cura-
tive; third, complications; and fourth, sequelae.

Prophylactic Treatment.—After the skin has
been exposed to a degree of color sufficient to cause
a first or second degree burn (Dupaytren), the
immediate application of full strength solution of hy-
drogen dioxide will abort the pathological changes.
I demonstrated this fact during the treatment of
numerous individuals who had come into contact
with hot steam pipes.

Curative Treatment.—The curative treatment of
burns depends upon the degree, the site, the area
involved, and the nature of the causative agent.
Pain must be relieved by the employment of mor-
phine hypodermatically or other suitable anodynes.
Stimulants as strychnine or ammonia are indicated
frequently to combat shock. Elimination and nu-
trition must be maintained. In the treatment of
burns produced by caustic acids or alkalies appro-
priate chemical antidotes are indicated.

The armamentarium of remedies for local therapeu-
ctic use contains Sodium bicarbonate (saturated
solution or as a dusting powder); picric acid (one
per cent. aqueous solution or in the form of a five
per cent. ointment); phénol sodique in a one to
eight solution; zinc oxide ointment, or iodo-
form; solution of hydrogen dioxide; saturated solu-
tion of boric acid; Sens's powder (three parts of
boric acid and one part of salicylic acid); iodoform;
solution of potassium nitrate; Carron oil; collodion;
boric acid and starch; salicylic wool; corrosive
sublimate solution, one to two thousand; carbonized
oil, one to forty; phenol ointment; ichthyol oint-
ment; tincture of calendula, five c. c. to 500 c. c.
of sterile water; ointment of boric acid; petrola-
tum; and cataplasm of kaolin.

When a patient is to be treated for a severe burn
he should be put to bed at absolute rest, the clothing should be cut away, warm blankets wrapped around the unaffected areas, and hot water bags or the electric pad applied to the unburned parts. Vesicles and blisters should be punctured with a sterile needle or scalpel. Sloughs and dead skin should be removed, employing a stiff brush, razor, or curette for the purpose. General anesthesia may be required. Brewers' yeast dressings facilitate the separation of necrotic tissue. After the sloughs have been separated and the surfaces are granulating, skin grafting is necessary. Continuous immersion in warm water is the most serviceable remedial measure in extreme cases. The water must be frequently changed and sodium chloride or some mild antiseptic may be added with advantage.

The choice of local remedies to be used depends upon the individual case and the judgment of the attending physician.

Complications.—The complications of burns, which require therapeutic notice, are, among others, duodenal ulcer, laryngitis, bronchitis, pneumonia, edema of the glottis, sepsis, pneumonia, septicemia, inflammatory fever, congestion of the viscera, intestinal perforation, and peritonitis.

Sequela.—The sequela to be considered are anemia; asthena; contracted, disfiguring, and painful cicatrices, keloid, and epithelioma. Troublesome scars may be prevented by early skin grafting and proper splinting.

Dr. A. H. Powers, of Boston, says:

Burns are of varying degrees and the treatment of them can best be given under three heads: moderate, serious, and severe.

The moderate burn.—There are many of so slight a degree that they do not need or at least do not receive a physician's attention. The moderate burns may be of limited or extended area. They result in some blistering of the skin and cause much discomfort, but are rarely fatal of themselves. Such a burn occurring in an old or diabetic person may, however, be serious enough to overcome the organism. In such cases moderate stimulation with appropriate remedies may be indicated, but in the moderate burns, as a rule, only local care is needed.

The first thing in order is to carefully sterilize the skin of the involved area. This may be done by a bichloride of mercury or carbolic acid solution, or, in cases where the skin is unbroken, alcohol may be used with great benefit. A carbolic acid solution has the advantage of being somewhat anesthetic and lessens or obliterates the pain for some time after its application. I prefer that all cleansing washes be as hot as can be borne, since the contraction of the vessels by the heat lessens the congestion for some time. When the skin is sterile, or practically so, some protective dressing must be applied, and sterile gauze with just enough of a simple sterile cerate to prevent the sticking of the dressing is usually all that is necessary.

The serious burn.—Serious burns are deeper and of considerable extent. In these cases the same careful cleansing of the skin or damaged area is absolutely necessary. Much care and time may well be spent in sterilizing the field at the first dressing. There may be need of care at the subsequent dressings, but the first is the most important. This is especially true, since in about three days granulations form and a granulated surface is not likely to absorb much sepsis. Here, too, protection is necessary and I had almost said imperative, and it is imperative for the best results. In this class of burns pain is much more marked and hence a sedative dressing is very helpful. Iodine in from five to ten per cent. in a cerate applied on sterile gauze often is ideal, and in other cases a dry dressing of boric acid finely powdered may prove acceptable.

The severe burn.—The severe burn is the supreme test of the ability of the physician. Here we often have severe shock, which may develop at any time in the first three or four days. Often prompt and active stimulation is necessary, and strychnine often seems to serve very well. But all conditions must be met and met skilfully and promptly. I have an idea that this shock is caused in part, at least, by the toxins in the burned area being absorbed and therefore the absolute need of a sterile field, if we are to lessen to the full extent the shock which may prove fatal. Next comes protection and here oftentimes the pain is apparently not as severe as the character of the burn would indicate. Sterile protective dressings must be applied and changed as often as the case may demand, which may be three or four times a day. In this class of cases the local treatment largely consists in applying sterile dressings, and keeping the field sterile till healing has taken place. One method of treatment, in the deeper burns where the area is considerable and scarring would be considerable, is by skin grafting. After a week or possibly ten days, the line of demarcation between the living and dead tissue appears and then, with a scalpel cut out the sloughing tissue and apply grafts after the method of Thiervel. In ten days, if the work is skilfully done, the area will be healed and the long tedious dressings will be unnecessary. The healed surface will be much more nearly normal and serious contractions will be avoided.

(To be concluded.)

Therapeutic Notes.

Treatment of Gastrointestinal Presclerosis.—I. V. Chetchkine, in Semaine médicale for February 5, 1913, is credited with pointing out the fact that frequently in patients between thirty-two and forty-five years of age, and occasionally in those who have passed this period, there occurs a combination of symptoms neither representative of any well recognized gastrointestinal disease nor of neurotic origin, but actually caused by a presclerotic condition in these organs. These symptoms consist of pain, two or three hours after meals, nausea, anorexia, bad taste in the mouth, occasionally vertigo and insomnia, and some abdominal tenderness. The heart sounds are frequently muffled, the second aortic, however, accentuated; the pulse is hard, the vessels indurated, and the skin flaccid or wrinkled. Pyrosis, vomiting, and alvine disturbances are conspicuously absent. Various drugs.
such as bromides, codeine, bismuth, phenyl salicylate, etc., have usually been tried in these cases without the least benefit.

In a series of 330 cases the author found theobromine sodium salicylate useful in about one third of the patients. Potassium iodide proved ineffective. The following mixture was found more beneficial than any other preparations used:

R Adonis vernalis, ... 5vi (8-10 grammes); Water, .................. 3vi (180 grammes);
Make an infusion, strain, and add.
Codeine, ............... gr. ½-iv (0.02-0.25 grammes);
Tincture of valerian, ....... Mxxv (1.6 grammes);
Compound spirit of ether, ....... 5i (64 grammes).
M. S. One dessertspoonful in milk three times daily.

This mixture was generally administered for three or four weeks. In a small proportion of cases the adonis caused digestive disturbances; this was soon overcome, however, by adding to the mixture two drachms (eight grammes) of tincture of convulsive. All the symptoms of the "presclerotic" condition were relieved.

Treatment of Whooping Cough.—M. J. Yakovlev, in Semaine médicole, April 16, 1913, is stated to have obtained striking results in three cases of pertussis in infants by the ordinary procedure of vaccination. The children thus treated were twelve, seventeen and eighteen months old, respectively, and were vaccinated on the fourth, seventh, and seventeenth day of the disease. In a week the frequency and intensity of the paroxysms was in each case greatly diminished, and in two to three weeks the complete recovery. Trial of vaccination in cases of whooping cough in children that had already been vaccinated showed it to be without effect under these conditions. The procedure is thus of value only in previously unvaccinated infants. Because of this fact Yakovlev, in the institution with which he is connected, is inclined to avoid early vaccination of infants in order that in the event of an epidemic of pertussis, with its high mortality among the very young, an efficacious measure of treatment shall be available.

Treatment of Gravess's Disease.—R. O. Moon, in the Practitioner for October, 1912, states that while in many cases it may be advisable at the outset to keep the patient in bed for several weeks, often an entire change of air, scene, and social circumstances will prove to be one of the best remedies. With regard to climate it is important to avoid great altitudes, and to remember that heat is badly borne by these patients. Long journeys should be forbidden.

The diet should be simple and mainly vegetable. It may be worth while to try the effect of drinking water different from that of the locality in which the disease was developed.

As to drugs, the author has had best results with moderate doses of arsenic and sodium bromide:

R Liquori potassii arsenis, ..... i.iii (0.2 grammes);
Sodii bromidi, ....... gr. x (0.6 grammes);
Aqua, q. s. ad ......... 3i (30 grammes).
M. Sig.: Three times daily.

Belladonna is sometimes helpful in quieting the general nervous etiologies. Some strongly recommend sodium phosphate.

One cannot as yet make any positive pronouncement on the subject of x-ray treatment. In obsti-

THE TREATMENT OF HEAT EXHAUSTION AND HEAT STROKE.

Judging from the routine treatment employed by many in the disorders caused by excessive heat, there is good ground for the belief that the clinical difference between heat exhaustion and heat stroke is too often overlooked. Were the treatments of these two conditions similar, no harm would result, but as this is far from being the case, the identification of each disorder as a distinct entity is of major importance. A few lines on this topic and the therapeutic and prophylactic measures indicated, will therefore be in order at the present time.

In heat exhaustion, as is well known, we are dealing with an asthenic collapse characterized by more or less sudden failure of the circulation. The blood accumulates in the great splanchnic area, depleting the brain and the peripheral tissues. Hence the pallor, vertigo, faintness, clamminess, coldness, etc., and the characteristic early hypothermia, the temperature falling often to 95° F. If we now compare this condition with the pathogenic phenomena of heat stroke or heat apoplexy as it is sometimes termed, the difference between them will become evident. Instead of the extreme vasodilation which occurs in heat exhaustion, there is extreme vasoconstriction in heat stroke; the condition being due, as emphasized long ago by Lambert and the late Ira Van Gieson, to autointoxication. The symptomatology is quite in keeping with the intense vascular erethism through which the blood is driven forcibly to the cerebrospinal system and the periphery. The characteristic symptom here is hyperpyrexia, the temperature reaching, in some instances, as high as 113° F., with intensely flushed, hot and sometimes cyanotic skin, injected conjunctive and in some cases convulsions, the result, in turn, of intense cerebrospinal hyperemia.

That the treatment of the two conditions, though both are due to excessive heat, should be antagonistic is selfevident. While in heat exhaustion the object should be to raise the vascular tension and cause the blood to return to the cerebrospinal system and the periphery, in heat stroke the aim should be to depress the vascular erethism and relieve the cerebrospinal system, lungs, and all peripheral tissues, of the intense congestion to which they are being subjected. It is in heat exhaustion, therefore, that strychnine, digitalis, aromatic spirit of ammonia and other stimulants are indicated. The ice bath here is an absurd measure; the skin has cooled itself sufficiently by inducing reflexly, through the heat and vasomotor centres, a hypothermia of over three degrees! A warm bath is indicated if any is used at all. In a shady, cool place, with the clothing loosened or removed, such a patient will promptly respond to the above stimulants. Conversely, the ice bath—or better—affusions of ice water combined with frictions until the temperature is reduced to 102° F., a procedure which gave O'Dwyer the lowest mortality on record—is the dominant therapeutic factor of heat stroke. Ice water enemas, hypodermyosis and the ice cap are potent adjuvants, while no threatening case should be deprived of the most active cerebrospinal depletant, lumbar puncture, which has now received the sanction of several authorities.

The prophylaxis of both conditions is so well known that mention will only be made here of the need of restricting the diet, avoiding particularly the use of foods rich in nucleins, meats, eggs, etc., during heat spells, and also all alcoholic drinks. Water and buttermilk are excellent summer beverages, the former to facilitate the elimination of waste through the kidneys, the latter to prevent intoxication from the alimentary tract.

MEDICAL SURVEY OF AMERICAN INDIANS.

On January 23 the surgeon general of the United States Public Health Service sent to the Senate a special report embodying the results of a widespread investigation by the Public Health Service into sanitary conditions and the prevalence
of disease among the North American Indians. Congress appropriated $10,000 for this survey on August 24, 1912, and fourteen medical officers specially trained for the work have been engaged until now in collecting data.

In general, the results confirm the less complete annual report of the Indian Office for the fiscal year 1912. Tuberculosis and trachoma are found to be the most destructive and serious diseases. Sanitary conditions on the reservations are very poor and require improvement, especially in housing arrangements and the living habits of the Indians. It is pointed out that grave danger exists of trachoma and tuberculosis being transmitted to the white race because of the increasing intercourse taking place between whites and Indians. The Indian is now in a gradual process of assimilation, which is furthered by the many reservation counties being opened to white settlement. Increasing facilities for transportation also tend toward spreading these diseases.

Conditions in regard to trachoma are truly astonishing. Reservation and nonreservation boarding schools in twenty-five States were visited, and a total of 39,231 Indians were examined, about one-eighth of the Indian population of the United States. Of these, 8,940 were afflicted with trachoma, or 22.7 per cent. of the entire number. If this rate prevails throughout the 322,715 Indians under the Indian Office, as seems probable, it means that 72,000 Indians in the United States have trachoma. The incidence of this disease varies greatly in different sections of the country. In Oklahoma 68.6 per cent. of those examined were trachomatous. In New York but two out of 943 had the disease. Trachoma was found more prevalent in the Indian schools than in the reservations from which the pupils came. It seems likely, therefore, that the schools are foci of contagion, and that pupils in many cases could contract the disease there and then introduce it into their home localities. The incidence was heaviest in children of school age, over one half of the subjects of the disease being between six and twenty years of age. In a group of 23,560 Indians 3,505 had trachoma, and 537 had sustained serious damage to vision. One hundred and forty-one were blind in one or both eyes. In most schools trachomatous children mingled freely with the others.

For several reasons it was difficult to obtain exact figures regarding tuberculosis. The time allotted for the work was very short and the territory to be covered very extensive. The regulation of the Indian Office excluding tuberculosis children from these schools is well observed, and therefore a large group of those examined showed an artificially lowered incidence of tuberculosis. Nevertheless, it was demonstrated that the presence of tuberculosis among the Indians is much in excess of that in the white race. The situation is so serious that immediate and vigorous measures are required for its relief. The highest proportion of infection with tuberculosis was found among the more primitive tribes; so among the Piutes of the Pyramid Lake reservation of Nevada the rate of incidence was 32.6 per cent., while the lowest incidence was in New York, with a case rate of 1.27 per cent. Of the children examined among the Jicarilla Apaches in New Mexico, 95.5 per cent. responded to the von Pirquet reaction.

Strangely enough, typhoid fever is exceptionally rare, no case being encountered in the survey, and the records showing the disease to be very infrequent. Smallpox is practically negligible, and scarlatina and diphtheria are rare, while measles and whooping cough have a wide incidence.

The surgeon general’s report makes definite and constructive suggestions as to methods of meeting the situation. He urges the point that improvement of the Indian’s economic status, making him independent and self supporting, and thus assuring him a sufficient and regular food supply, is a most important consideration. Education in personal and domestic hygiene should be prosecuted vigorously along every effective line. It is recommended that the Indian Medical Service be greatly extended in its duties and powers, and that the Indian country be subdivided into sanitary districts, according to size and density of population, each with a medical officer who shall be directly under the charge of the chief medical officer for the reservation. Reservation hospitals and movable clinics for trachoma and tuberculosis, separated, should be maintained, and also a sufficient number of field nurses, under the direction of the medical officers, to provide home treatment and instruction for such as cannot attend the clinic or hospital, and children suffering from tuberculosis or trachoma should be in separate schools.

THE NATURAL HISTORY OF PELLAGRA.

Louis W. Sambon, who first postulated the theory that pellagra was a protozoal disease transmitted by an insect, now brings forward some very suggestive collateral evidence in support of his views in the British Medical Journal for July 5, 1913. He incriminates the small biting fly, of the species known as the Simulide, which inhabit only those regions in which there are swiftly moving streams. In these streams the insect passes its larval stage. As the result of a most painstaking and extensive study of the natural history of the disease, Sambon states that pellagra, like malaria,
sleeping sickness, and other endemic diseases, has its scattered, strictly limited districts, invariably and necessarily associated with the same peculiar ecological conditions. In these districts the disease is rampant and affects newcomers; outside of such regions the disease cannot be contracted, notwithstanding close, and intimate contact and association with emigrant pellagrins. Within such endemic stations the disease attacks all ages, both sexes, and entire families; outside such stations the disease involves only occasional and isolated individuals, never affecting children who have not been out of the free region. That persons recently settled in a pellagra district almost inevitably soon become infected is held by Sambon to be one of the strongest points in favor of his hypothesis. Such occurrence he has observed repeatedly. He goes even farther, and cites several instances of infection having occurred during a single brief sojourn of healthy individuals in such a pellagra locality; in some the period of stay was less than a month, yet infection took place. Such infection usually takes place during the first epidemic season in the locality, soon after exposure to the infective agent, though the symptoms may be very slow in developing and not appear until long after the person has left the area. He says, "Therefore, in this respect, pellagra is analogous to malaria, yellow fever, sleeping sickness, and other infectious diseases, with well defined topographical limitations, which limitations are explained by and are dependent upon the biological necessities of their special insect intermediaries with corresponding topographical limitations." A most striking fact in support of Sambon's theory is found in the distribution of the disease in certain of the Venetian Lagoon islands. The small islet town of Burano entirely covers its islet, and, in contrast to towns in general, it is found to contain a large number of pellagrins. Here the pellagrins are almost exclusively men, neither women nor children being infected, as is usually the case in pellagra regions. This is accounted for by the fact that the men spend their days away from the island, fishing near the mainland, at the mouths of streams along which pellagra is very prevalent, and the air of which is filled with small biting midges. This source of the infection is further borne out by the fact that the men who work in the arsenals in Venice, although living on the same islet, are free from infection. Food supplies to this town are the same for all. One of the well known phenomena of pellagra is the annual recurrence of exacerbations of the disease in old cases. Such recurrences occur in the spring, at about the same time that the flies are beginning to emerge. From these recurrent old cases the flies obtain their infection. After an interval sufficient for the completion of the cycle in the intermediary host, these flies become infective for healthy persons, and we have an epidemic outbreak of the disease. Precisely such occurrences are to be encountered in Italy, and in other markedly pellagrous regions. Sambon believes that there is no adequate evidence for the toxic or dietetic theories of the causation of the disease, and, while he has not been able to find the causative parasite, he believes that the evidence in favor of the parasitic nature of the disease is extremely strong, if not absolutely convincing.

THE PROGNOSIS OF TUBERCULOUS MENINGITIS.

There are probably few who realize what a large number of deaths are caused annually by this disease. For instance, in the city of New York, it occasions far more than typhoid fever. Taking a year at random, we find that in 1909 no less than 806 deaths were accredited to tuberculous meningitis, or a weekly average of about fifteen and two fifths, while the deaths from typhoid amounted to 564, or a weekly average of about ten and four fifths. In 1912 the weekly average of deaths from tuberculous meningitis recorded by the Bureau of Vital Statistics was about seventeen and a half, and that from typhoid about nine and a half. During the first half of the present year, when fewer cases of the latter disease (as well as a smaller mortality from it) were reported than ever before, the disproportion was very much greater; the weekly average of deaths from tuberculous meningitis being the same as in 1912, and that from typhoid only about three and a half. Of course, recovery in tuberculous meningitis is a rare exception, but possibly in the future the outlook may be at least a little less gloomy. Dr. Robert L. Pitfield, of Philadelphia, who reports one case of his own (American Journal of the Medical Sciences, July, 1913), has been able to collect, from various sources, twenty-eight other new cases of undoubted tuberculous meningitis in which recovery followed, and eight others in which the diagnosis was less positive. If in any given instance the process should fortunately be limited to a part of the surface of the brain, there would, it appears, be some prospect of a successful issue under intelligent treatment. Doctor Pitfield's studies show that recovery can take place in perhaps one in 200 cases, and in view of this fact he urges that steps should be undertaken actively to facilitate such a possibility. In the treatment he would include prompt lumbar puncture, the free use of hexamethylenamine, morphine as an analgesic and sedative (provided respiration is not embarrassed by it), and one or two injections of tuberculin.
Jews Items.

New Hospital for Fort Worth, Texas.—A new hospital will be erected at Fort Worth, Texas, jointly by the city and county, at a cost of $20,000, of which $3,500 has been contributed by the city confederation of women's clubs.

Typhoid Fever in Evansville, Ind.—Acting Assistant Surgeon Neary, of the United States Public Health Service, reports that during the week ending July 26th, thirty-three cases of typhoid fever were reported in Evansville, making a total of 148 cases reported since June 14th.

Congressional Plans. —The Surgeon General, Brooks, of the United States Public Health Service, reports that during the week ending July 26, 1913, three cases of cerebrospinal meningitis were reported, making a total of eighty-two cases of the disease in Los Angeles since January 1, 1913.

Pelagra.—During the week ending July 12, 1913, pelagra was reported by cities to the United States Public Health Service, at Washington, D. C., as follows: Boston, Mass., 1 death; Buffalo, N. Y., 1 death; Montgomery, Ala., 2 cases with 2 deaths; Nashville, Tenn., 3 cases with 3 deaths; New Orleans, La., 3 deaths.

Philadelphia Bureau of Health Plans Extensions to Bacteriological Laboratory.—Plans have been prepared by the Department of Charities and Corrections of Philadelphia for making extensions to the bacteriological laboratory of the Bureau of Health, so that physicians can have specimens examined, and the results known, in a less time than is now required for that purpose. The aim is to broaden the services of the laboratory and to render greater help to the individual participating physician, as well as to the city in general. The additional receiving outfits, which will shortly be placed in the distributing stations, are to make it easier for physicians to have examinations made.

The Washington State Medical Association.—At the annual meeting of this association, held in Everett on July 14th, 15th, and 16th, the following officers were elected: C. W. Sharples, of Seattle, president-elect; Dr. J. R. Brown, of Tacoma, first vice-president; Dr. D. H. Palmer, of Seattle, second vice-president; secretary-treasurer, Dr. C. H. Thompson, of Seattle; trustees, Dr. W. N. Hunt, of Burlington; Dr. L. M. Sims, of Kalama; Dr. L. H. Redon, of Seattle; Dr. J. R. Yocom, of Tacoma; Dr. J. M. Semple, of Medical Lake; Dr. S. E. Lambert, of Spokane; Dr. C. N. Sutten, of Walla Walla; and Dr. L. Ganson, of Odessa. Next year's meeting will be held in North Yakima.

Seventeenth International Congress of Medicine.—Over seven thousand physicians from all over the world have met in London to attend this congress, which was opened on July 30th, with a meeting on August 6th, in Albert Hall, by Prince Arthur of Cumberland. The congress, which will be continued until next Tuesday, will bring together, it is said, the largest gathering of medical men that has ever taken place. About eighty American physicians are attending the meeting, the names of over one hundred being on the official program. Among the New York physicians who will take part in the proceedings are Dr. Robert Abbe, Dr. Simon Flexner, Dr. S. J. Melzer, Dr. Henry Koplik, Dr. Theodore C. Janeway, Dr. Russell Fowler, and Dr. Simon Sarban. Surgeon General Charles F. Stokes represents the United States Navy and Major Frederick F. Russell the army. A brief account of the proceedings of the congress will appear in a later issue.

Pennsylvania Medical Association.—Seventy-six physicians— representing the counties of the five counties comprising the fifth Censorial District of Pennsylvania — met in session in Gettysburg on July 24th, under the presidency of Dr. H. A. Spangler, of Gettysburg, and passed several resolutions. Among the resolutions was an address by Dr. F. X. Derick, of Philadelphia, on the Early Diagnosis and Treatment of Mental Diseases. York was chosen as next year's meeting place, and the following officers were elected: President, Dr. George E. Holtz, of York; first vice-president, Dr. F. L. S. Fairplay, of Carlisle; second vice-president, Dr. W. Van Camp, of Plainfield; third vice-president, Dr. J. J. Coffman, of Scotland; secretary and treasurer, Dr. Charles W. Eisenhower, of York.

The Federation of State Medical Boards of the United States will publish its first bulletin, the Quarterly, on October 1st, 1913. The bulletin will deal primarily with medical education and topics of general interest to State board examiners. Dr. O. V. Hoffman, secretary of the New York State Board of Examiners, is editor.

Cumberland Valley Medical Association Meeting.—The Cumberland Valley Medical Society, consisting of Adams, Franklin, and York counties in Pennsylvania, will hold its annual meeting on September 4th. This society was organized ten years ago, and is one of the largest in Western Maryland and Pennsylvania and has been holding its meetings in the different counties annually since that time. The scientific and social meeting will be held at the Country Club after which a banquet will be held. The following are the officers of the society: President, Dr. L. H. Keller; secretary, Dr. John J. Coffman, of Scotland; treasurer, Dr. R. Koons, of Mechanicsburg, will be at the head of the arrangements; Dr. V. M. Reichard, of Fairplay; Dr. A. C. Mains, of Hagerstown; Dr. J. B. Anderson, of Waynesboro; Dr. H. C. Lawton, of Camp Hill, Pa. The committee on programme: Dr. W. D. Campbell. Dr. L. M. Coffman, and Dr. H. A. Spangler, of Carlisle.

Gifts and Bequests to Hospitals.—By the will of Anthony N. Brady, the Allegheny County, the Allegheny General Hospital, the Phipps Memorial Hospital, the Presbyterian Hospital, the Children's Hospital, and the Allegheny General Hospital, the United Hospital, the Presbyterian Hospital; the University of Michigan Hospital; and the Allegheny General Hospital; St. Peter's Hospital, all of Albany, N. Y., will each receive $25,000.

By the will of Miss Elizabeth L. Lewis, late of Philadelphia, the Presbyterian Hospital, will receive $100,000, which is to be divided among several buildings purposes and half for maintenance. In addition to this bequest the Presbyterian Hospital will receive $5,000 to endow a bed in memory of Sarah S. L. Brodeh.

Mrs. Anna Moore, who died in New York on July 17th, left her entire residuary estate, amounting to more than $800,000, to establish a home for convalescents.

Mrs. E. H. Harriman has donated $10,000 to the fund created by her for research work carried on by the Southern Pacific Hospital in San Francisco.

Personal.—Dr. Frank P. Norbury, alienist to the Board of Administration of Illinois, has tendered his resignation, to become effective on October 1st. Doctor Norbury will enter upon consulting practice at Springfield, Ill.

The title of emeritus professor of chemistry has been conferred upon Sir William Ramsay by the University of London.

Dr. Arthur Allison Howard, of Boston, has been appointed physician in chief of the hospital for children and of the children's medical outpatient department of the Boston Dispensary, succeeding Dr. William Palmer Lucas, who has resigned to become professor of medicine in the medical department of the University of California.

Dr. Leo T. Myles, of Cambridge, Mass., has been appointed a United States examining surgeon for the Department of the Interior in Middlesex County.

Dr. Patrick M. Kelly, of Litchfield, Ill., has been appointed superintendent of the Kankakee State Hospital for the Insane, succeeding Dr. Sidney D. Wilgus, who resigned on August 1st.

Massachusetts Association of Boards of Health.—The quarterly meeting of this association, which is comprised of the several boards of health of the towns of the State, took the form of an outing at Gallop's Island, on Thursday afternoon, July 31st. Dr. Samuel H. Durgin, president of the association, opened the meeting, which was presided over by Professor William T. Sedgewick, of the Massachusetts Institute of Technology. Dr. John M. Anderson, director of the hygienic laboratory of the United States Public Health Service, read a paper on the Organization, Powers, and Duties of the United States Public Health Service Today. Dr. Arthur Reed Perry, of Washington, who has been investigating the health and mortality statistics in the cotton industry of Massachusetts, summarized his findings in a paper entitled A Recent Contribution by the Federal Government to Prevent and Ward Off Disease, which was prepared in a paper entitled An Experiment in Public Health Administration in Massachusetts, dealt with the growing tendency toward and necessity for specialization and cooperation in matters of public hygiene.
The Effect of Light on Metabolism.—L. Pincussohn explains that while we have some knowledge of the influence of light on metabolism, no data are available as to what changes take place in the intermediate stage. It is known that the ferments are influenced by the rays, especially those of the violet and ultraviolet part of the spectrum, and that altogether there results an increased oxidizing power. The author has made some experiments on dogs to note the change made by light rays on purin bodies. The injection of sensitized coloring matter complicates the action of light by a photodynamic process (Tappeiner). The light was found to bring about a great change in purin metamorphosis. The allantoin excretion is markedly diminished under the influence of the rays. Exposure for about ten hours daily causes the decrease of allantoin products to continue for several days after withdrawal from the rays, only to again slowly increase. As to the detection of stones in the ureter, phleboliths, peosal calcinations, etc.—stones in the ureter are best distinguished when their movability is made apparent after cystoscopy by the radioscope, taking for granted that the stones are not impacted. On the whole, radiography, as only one of the methods of clinical examination, should be valued and critically judged as other methods are.

June 9, 1912.

General Histological Changes in Tissues under the Influence of Rays.—L. Wickham demonstrates the following: It seems that in comparing x rays with those of radium, an approximately real analogy may be shown to exist. In the effects on the skin, where the histological action of actinic, Finsen, and sun rays are studied, there is a strong resemblance of action between radium and the x ray. It is true, however, that these analogies do not exclude certain differences. The following are the fundamental facts which more or less combine to advance proliferation or destruction of cells: 1. The degree of sensitiveness of the cell for the rays. 2. The amount of ray absorbed in a given time. A dose quickly absorbed must act differently from the same dose slowly absorbed. 3. Special characteristics of different rays. 4. The time passed between the end of the ray and the histological determination. When we compare the changes effected by the x ray and the radium ray on epithelium, on the one hand, and on sarcoma on the other, these are found to be brought about constantly by the same process. The cell dies in what the author terms a state of monstrosity, and is carried off by the phagocytes. The regenerative hypertrophy of the sarcomatous elements appear to be more apparent than the epitheliomatous elements. The experiments carried out show that: 1. Heliotherapy is an essential (in the way of therapeutic advance) in the conservative treatment of surgical tuberculosis. 2. The treatment with heliotherapy is best effected at the seashore. 3. Along with the sunshine, other valuable properties are afforded by sea air; so that when the healing process has been begun by means of insolation, it continues independently. 4. The heliotherapy of surgical tuberculosis must be carefully carried on in a well selected place at the seashore and in a building specially constructed and adapted to the purpose; and also under surgical and orthopedic supervision.

June 16, 1912.

The Independent Life of Tissues and Organs.—A. Carrel shows how various tissues may be cultivated in a plasma of certain degrees of concentration. Fragments of the heart, skin, and peristome of an embryo chicken, and also portions of the organs of a grown chicken, a dog, and a mouse were used in his experiments. These were cultivated in more or less concentrated quantities of fluid. It was proved that the amount of growth varied in direct proportion to the concentration of the fluid. Several drops of Ringer's solution when left mingled with the embryonal tissues for several minutes increased their growth double and triple, A still greater increase of growth occurred when the tissues had been in contact with the Ringer solution for several days. The concentrated extract increased the rapidity of growth from twenty to thirty times. The effect also differed with the nature of the tissue. The embryonal tissues were most sensitive, whereas the heart and kidney tissues were not as readily affected. It was decided that the cells have an influence on the media in which they develop. Growth discontinues in all cultures of cells, as well as in cultures of microorganisms, and they die because the medium exhausts itself and becomes overladen with the products of cell secretion. Upon this hypothesis the extension of the life of the tissues might be made limitless. These results permit us to think of the possibility of using an organism, cell colonies of tissues which were fitted in life, as reagents, with dynamic capital.

The Digestion of Lecithin in Disease of the Gastrointestinal Canal.—R. Ehrmann and H. Kruspe report that a greatly increased amount of lecithin is present in the feces when the flow of bile is obstructed from the intestines. In jaundice, therefore, the fats are decreased; but food rich in lecithin, as yolks of eggs, brain substance, etc., are given. The physiological processes in the healthy show how great the loss of lecithin is in icterus. This points out how lecithin does not pass solely to the pancreas, to be split up into its component parts, glycemic phosphate, cholien, and fatty acids. Without being previously split up, it is for the most part absorbed directly in the intestinal tract as lecithin. Here is found the origin of the therapeutic prescribing of lecithin, and its entire failure to split up in the intestines in the absence of bile.

Histopin.—E. Saalfield states that the fluid histopin is a harmless remedy for immunizing the tissue surrounding furuncles; further, that it exerts a favorably palliative influence on syecosis vulgaris. This last is also observed in the use of histopin ointment, which may also be considered a specific in impetigo contagiosa except in those rare cases where staphylococci and streptococci are believed to be etiological factors.

June 23, 1912.

Bath Therapy for Circulatory Disturbances.—O. Muller emphasizes the importance of a proper
combination of theory and practice in this branch. Theory, he says, gives the practitioner confidence in treating patients. It gives him the after impression and penetrative power of methods scientifically thought out. Practice gives the theorist a large part of his mission and the absolutely necessary probing of medicine, on the whole. This is why physicians who are theorists should always have the practical in mind and those who are practical physicians should not lose sight of theory. In connection with a reference to many kinds of baths and their effects, the author mentions certain contraindications. These apply to patients who suffer from dyspnea while at rest, to the more advanced cases of edema, and also to those with effusions or extravasations from bodily orifices, advanced angina pectoris, and the more severe cardiac asthma. Baths are contraindicated in all conditions which might lead to emboli or hemorrhage, for patients with larger aneurysms, and for those with high blood pressure (180 to 190 mm. Hg.). These, especially, should not have cool baths. Great physical weakness is also a contraindication.

June 20, 1915.

The Influence of Calcium Salts on Constitution and Health.—R. Emmerich and O. Loew state that calcium compounds enter into the composition of not only teeth and bone, but also of various organs of the body, as heart muscle, glands, and the cerebrospinal system. Along with several other hypotheses concerning the use of calcium salts, a characteristic action on plants is described which throws light on the most valuable function of calcium. 1. There is no marked division between plant and animal forms, since the higher flagellate constitute a link connecting the lower levels of both kingdoms. 2. Oxalate of calcium and fluoride of sodium are not only poisonous to plants, but to all animal life. According to F. Winkler, both salts bring about a prompt cell destruction of leucocytes, which is not the case with tartrate of calcium. 3. The red blood corpuscles of mammals possess no nuclei and are also free from calcium, while the red blood corpuscles of birds have nuclei and, according to Thorhammer, are also found to contain calcium. 4. The calcium content of animal organs grows in accordance with the mass and size of the cell nuclei. The gland and ganglion cells contain from three to four times as much calcium, in accordance with their size, as the muscle cells of mammals poor in nuclei. Muscles of fish contain larger nuclei than those of mammals and their calcium content is accordingly much greater.

WIE.NER KLINISCHE WOEHENSCHRIFT.

June 12, 1915.

Tuberculin Treatment of Bronchial Asthma.—Otto Frankfurter says that there is a causal connection between bronchial asthma and tuberculosis, and that a systematic treatment with tuberculin may reduce the number of attacks, if persisted in sufficiently long.

June 19, 1915.

Relation of the Bacillus Perez to Ozena.—Gustav Hofer calls attention again to the Cocobacillus farotidus ozena described more than a decade ago by Perez in Buenos Aires. This bacillus is small, polymorphous, stains well with the usual aniline colors, is Gram negative, does not liquefy gelatin or coagulate milk, induces ammoniacal fermentation of urine, and the cultures emit the typical fetid odor of ozena. Hofer confirms the assertion made by Perez, that this bacillus can be found in most cases of ozena in man, and that it induces in animals a trouble in the nose which is apparently identical. This Hofer considers to be a great advance, as a bacteriological examination will enable the diagnosis to be made at an early stage of the disease and may render prophylaxis possible, as well as an etiological therapy.

Psychotherapy in Practice.—Rudolf Hatschek is inclined to think Freud’s methods of psychanalysis to be lacking in a scientific basis and mentions some cases in which harm was done by their application. One of these cases was that of an elderly neurasthenic whose condition was made materially worse by dwelling upon the masturbation he had practised during youth. In another case investigation, according to Freud’s method, led nearly to suicide. He says that the method is undergoing changes at present, and thinks that something useful and practicable may be derived from it when the motives are not limited to sexual impulses. Systematic psychotherapy, along the lines laid down by Dubois, he thinks is very important, second only in neurology to operative and antisyphilitic measures. It can be applied more widely than either of these. It requires great perseverance and patience, together with a special sympathy and a certain optimism on the part of the physician in order to succeed. In dealing with the neuroses optimists make the best physicians.

Coxalgic Attacks in Childhood.—Friedrich R. von Friedlaender says that an attack of pain in the hip joint should lead us to suspect tuberculosis when it is accompanied by a clearly perceptible atrophy of the muscles of the hip and thigh, when the leg is either lengthened or shortened, when there is a swelling of the joint and of the glands in front of it and on the psoas, and when the disease has been preceded by a change in the physical and psychic condition of the child. When the sciatic and crural nerves are tender, both trochanters are abnormally high, there is no atrophy of the muscles, the joint itself is painless, and there is contracture of the flexor and abduction muscles, with concentric limitation of their excursions, suspicion should be directed toward an irritation of the joint produced by static conditions. When the hip exhibits a sudden and painful flexion contracture with abduction or slight adduction; when the joint is slightly swollen and tender and its movability somewhat impaired, while the glands are not affected and there is no muscular atrophy, the possibility of a benign ephemerical coxitis must be taken into account. The probability of this assumption is increased when the attack is preceded by an inflammation of the respiratory tract, and the symptoms disappear quickly, but the diagnosis will be made positive later by the demonstration that the leg has been lengthened.

The Weight of the Fetus and the Nutrition of the Mother.—Josef Bondi believes as a result of his investigations that the fetus draws what it needs from the mother without regard to the condition of her nutrition, and that its growth is independent of her condition, the same as the growth of a malig-
nant tumor. In lactation also he finds the milk to be independent of the nutritive condition of the mother. Fat, well nourished mothers often have little milk, while thin, badly nourished women may have plenty of good milk. The three influences that he thinks affect the size of the child at birth are: 1. Heredity; 2. the age of the mother (the older the woman the larger the child); 3. the glands with internal secretion in both the mother and the fetus. His conclusion is that the size of the child cannot be influenced by dieting the mother. The diet in pregnancy should be exactly the same as that for normal women.

ZEITSCHRIFT FÜR UROLOGISCHE CHIRURGIE.
March, 1912.
Perinephritic Tumors.—F. Oehlecker had a patient with a right sided abdominal tumor. The diagnosis lay between tumor of the gall bladder, liver, and kidney. Urine catheterism showed normal urine from either kidney and normal function of each. Radiography after bilateral injection of the kidney pelvis with collargol showed the following: The left kidney pelvis was normal in position and shape and showed a slight kink at the apex of the pelvis. The right kidney pelvis was on a level with the crest of the ileum and the calices pointed downward, instead of inward. A diagnosis was made of a probable perinephritic tumor pressing downward the right kidney. At operation such a tumor was found and removed. The normal kidney was found depressed with the pelvis pointing downward. The left kidney was exposed and found to be normal, but a tumor of the suprarenal body was found. The right tumor was removed, and death occurred the second day after operation. Both tumors were found to be hypernephromata. The author calls attention to the value of pyelography in the differential diagnosis of tumors in this region.

Collargol Injection of the Kidneys and Kidney Pelves.—G. Strassman has injected collargol into the kidney pelvis of dogs to find out how long the collargol remains in the pelvis and whether it has any harmful effect upon the kidney. His experiments showed that after twenty-four hours there was practically no collargol left in the pelvis; that if care was used in not injecting the collargol under too much pressure no harm and no particular alterations of the kidney pelvis resulted. He tells of a case of Oehlecker, who injected collargol under high pressure into the kidney pelvis of a patient. Pain and moderate rise of temperature resulted. Five days later the kidney was extirpated and showed small areas of necrosis due to the collargol. He also refers to a case of Cachrission’s where the radiograph showed collargol in the tubuli recti. The patient had five days of pain in the kidney region and fourteen days of fever. Rossli had a case in which the patient died five days after collargol injection. The result of the autopsy showed that death was due to collargol poisoning.

PRESSE MÉDICALE.
July 6, 1912.
Lung Infection from the Umbilicus.—E. Boumaire and G. Durante assert that infection of the lung originating at the umbilicus in newborn infants is a far more frequently occurring condition than has been generally realized. Latent infections of the umbilicus are often overlooked as a cause of acute and even chronic disease of the viscera. After the liver, the lung is the organ most frequently involved from this source. Three forms of lung disorder are recognized by the authors, the first including primary toxic lesions, manifested as violet colored patches of the lung tissue, variable in size, and due merely to the action of toxins on the vessels, attempts at bacterial culture regularly failing. Septicemic lesions may occur as miliary infects, with or without a surrounding zone of congestion, as foci of hepatization, or even as lung abscess or pleurisy; the bronchial tubes are characteristically intact, and there are bacterial emboli in small vessels, though, different from bronchopneumonia of respiratory origin, no bacteria can be found in the air cells. Occasionally, a third form of lung affection is seen, consisting in infants that have recovered from the umbilical infection, but succumbed to other accidental causes of pleural thickenings or areas of sclerosis in the lung, representing old healed infects. Regarding the diagnosis of these lung conditions, in general, the authors assert that careful auscultation and percussion are usually sufficient. Absence of pulmonary symptoms, however, does not signify definitely that the lungs are normal. Early septicemias no sign of umbilical infection may be apparent, or even may become manifest only after the visceral symptoms. Jaundice in the newborn preceded by an obscure rise in temperature and followed by the lung symptoms, is characteristic of umbilical infection.

July 9, 1912.
Abnormally High Erythrocytic Resistance.—E. Well and A. Dufourt point out that while lysins in the blood are often capable of impairing the resisting power of the red corpuscles, sometimes, on the contrary, they lead to increased resistance on their part—a manifestation of adaptation of the red cells to the prejudicial medium they inhabit. This adaptation is not immediate, as there is time for a more or less marked preliminary loss in red cells, with consequent anemia, to occur. The authors report cases of purpura, scarlatina, measles, pneumonia, etc., showing that the increased erythrocytic resistance may develop, not in the presence of a lysin active against the patient’s own corpuscles, but of one destructive to the corpuscles of different individuals of the same species. The research as a whole points to erythrocytic resistance as being a subsidiary of other conditions present; that which determines its extent, and which must be investigated with care, is the condition of the serum itself as to lysins.

Reflex Contractions of the Colon Occurring upon Excitation of the Stomach.—H. Lebon and P. Aubourg report experimental work performed with the aid of radiography in human beings on this subject. The contractions of the large intestine consequent upon the injection of food may be due to one of several causes, and are not necessarily reflex contractions. They vary according to the substances ingested. The effect on the colon of mere contact of a foreign body with the gastric mucosa was observed under the X rays in a patient that had received bismuth with rice the day before.
Gentle rotary movements of a tube previously passed into the stomach very soon caused contractions of the ascending and transverse colon. Ingestion of oxbile failed to produce any effect, but ingestion of a cachet of powdered quassia induced colonic contractions in from six to eight minutes, while a dessertspoonful of water containing two milligrammes of quassia acted almost at once. Strychnine also acted in a short time. Ingestion of a solution of caffeine, or even of a cupful of strong coffee, brought about prompt contractions of the large intestine, driving the bismuth laden contents of the ascending colon toward the ileac colon, without association of any movements of reverse peristalsis. These movements were still continuing when the observation was stopped, twenty minutes later, and obviously account for the good effects noted by certain constipated individuals from the ingestion of coffee at breakfast.

**SEMAINE MÉDICALE.**

*July 9, 1913.*

**Military and Civil Treatment of Abdominal Wounds Caused by Firearms.—** F. Lejars discusses the question whether, in view of the favorable terminations frequently witnessed in recent war practice after nonoperative treatment of abdominal wounds, less insistence should not be placed than is now customary upon operative treatment of like wounds in civil life. The conclusion reached is that nonintervention is, at best, but an imperfect practice imposed by war conditions, and should not be countenanced in civil life.

**ROUSKY VRATCH.**

*May 4, 1913.*

**The Action of Ultraviolet Rays on Enzymes.**—N. O. Ziber-Shumova found that ultraviolet rays inhibit to some extent the activity of the various enzymes.

**The Influence of the Removal of Some of the Ductless Glands on the Growth of Sarcoma in Dogs.**—V. G. Korentsevsky found by experiments on dogs with artificially induced sarcomas that the maximum growth of the tumor occurred in dogs subjected to either thyroidectomy or castration, the removal of either of those glands apparently favoring the development of tumors. Degeneration and absorption of the tumor occurred early and were particularly marked in dogs that were both castrated and thyroidectomized.

**Influence of the Spermolysins and Ovariolysins on Impregnation in Animals.**—N. N. Alexeeff reports in a preliminary communication his experiments on guinea pigs, rabbits, and dogs which tend to show that the introduction of antispermatoxic or antiovaiotoxic serum prevents conception. He obtained the serum by immunizing animals with testicular or ovarian substance.

**Malignant Degeneration of Ovarian Cystsoma.**—K. P. Ulezko-Stroganova regards proliferative cystomas of the ovary as intermediary between benign and malignant tumors. The epithelial hyperplasia which characterizes these tumors renders them particularly liable to carcinomatous degeneration.

**Bacilli Carriers in Typhoid.**—S. L. Finkelstein reports the case of a trained nurse typhoid carrier who never had the disease herself, but was responsible for the occurrence of typhoid in two other nurses.

**The Nitrifying Bacteria of Biological Filters.**—M. N. Rubel shows by a series of experiments that fats and soaps act deleteriously on the nitrifying process which takes place in so called biological filters. He suggests that provision should be made for the removal of these substances from the sewage before it reaches the filters.

**Hemorrhages in Scarlet Fever.**—W. N. Kleimenko concludes from an extensive study of the literature and his own observations that hemorrhages in the course of scarlet fever may be parenchymatous (capillary), venous, arteriogenous, and arterial. It is caused by degeneration of the vessel walls and occurs principally in the neck, ear, throat, and the gastrointestinal tract. The hemorrhage takes place after the second week of the disease; may recur, and is generally fatal. The treatment consists in tamponade, when possible, and ligation of the vessels. As a prophylactic measure, the earliest possible evacuation of suppurating lymph glands is suggested.

**The Pathogenesis of Acute Pneumonic Forms of Pulmonary Tuberculosis.**—A. N. Rubel maintains as a result of experiments on animals that the varying forms of pulmonary tuberculosis, from the extensive, rapidly fatal, pneumatic type to slight involvement of the lung tissue, are due to different doses of the tubercle bacilli, and not, as supposed, to their varying virulence or the varying susceptibility of the host.

**The Diagnostic Significance of the Copper Coin Sound (Signe du sou) in Inflammation of the Lungs and Pleuritis in Children.**—S. E. Ostrovsky verified the Pitres sign in twenty-five cases of pneumonia and pleurisy in children. In uncomplicated pleuritic effusion the metallic sound was always transmitted through the affected area. In cases complicated with affection of the lungs the metallic sound was not so clear; while in cases of pneumonia, as well as in healthy lungs, the sign was negative. The author regards this sign as of great value in the diagnosis of pleurisy in children.

**Clinical Observations on the Action of Neo- salvarsan.**—A. N. Solovjeff employed neo-salvarsan intravenously in 260 cases, and concludes that it is practically nontoxic and also well tolerated. It improves nutrition. The injection should be repeated at short intervals and, when possible, used in connection with mercury.

**Complication of Typhoid Fever with Ascaris Lumbroicide.**—L. A. Zilberberg collected a number of cases from the literature and reports two of his own in which *Ascarides lumbroicide* appeared in the course of typhoid fever and were apparently responsible for perforation.

**CANADIAN MEDICAL ASSOCIATION JOURNAL.**

*July, 1913.*

**The Responsibility for the Advanced Case of Tuberculosis.**—C. H. Vrooman says that after discounting all such causes as neglect to apply for advice, inattention to proper advice, or acute onset of the disease, he estimates that at least fifty per cent, of the cases of advanced tuberculosis become
so because some general practitioner who saw them in the early stages failed to make the diagnosis, or, if suspecting the proper diagnosis, failed to recognize the serious significance of the symptoms and gave improper advice. "It is not in most cases want of knowledge, but rather carelessness in examination of the patient; trouble is not taken to strip the patient's chest and give him a thorough examination, the sputum is not examined often enough, and when the diagnosis of tuberculosis is suspected the doctor is not honest with his patient. A diagnosis of 'weak lungs,' 'general debility,' 'chronic bronchitis,' is often given when, if the doctor were honest, he would tell his patient at once that he strongly suspected tuberculosis, and proper steps should be taken to clear up the diagnosis."

**China Medical Journal.**

**May, 1913**

**Treatment of Bubonic Plague.**—P. J. Todd concludes a study of plague, the first portion of which was published in the January issue. In speaking of the treatment he says that the multiplicity of modes which have been employed throws a certain doubt on their value, especially as the mortality of the disease varies much according to the virulence of the virus, the period of the epidemic, and the race and age of the person attacked. Personally, he says, he does not remember one instance of recovery among all the cases of plague he saw during his first eight years in China; and not until he began serum treatment did he have a patient recover. Last year, out of thirty cases, twelve patients recovered under serum treatment and heart tonics. This year his supply of serum has been limited, and only ten patients were treated with it, but five of them are known to have recovered. His method is to inject from ninety to 100 c. c. in adults—one half intravenously and one half subcutaneously in the region of the bubo. In children about half this amount. Of late he has, in addition, adopted the plan of injecting pure phenol into the enlarged gland or glands—from ten to twenty drops (presumably of a saturated solution) for each patient. Also, he gives hexamethylenamine to its limit, i. e., until the patient complains of considerable irritation of the bladder. Two cases recently treated with hexamethylenamine and phenol injections (without the use of serum) have recovered. Good nursing combined with early confinement to bed, maintenance of the recumbent position to prevent syncope, and careful feeding and general treatment to maintain the patient's strength and prevent complications, if possible, are calculated to give the best results, either with or without serotherapy. Complications are treated on general principles. Notwithstanding the somewhat disappointing results of the serum treatment, it must be confessed that there is no better in the hands of the physician: for, in falling back on general treatment, no attempt is made to deal with the manufacture of toxine elaborated in the system. The struggle must be between the attacking force of the microbe and the resisting power of the patient, assisted by the skill of the medical attendant. Heart failure is perhaps the most important symptom to be contended against, and, personally, the author has found the administration of digitalis by the mouth and strychnine by subcutaneous injection much more effective than strychnine given hypodermically. To control the febrile symptoms and check delirium, ice bags to the head, sponging of the body, and the use of hypnotics which are not depressants are beneficial. The pain and tenderness of the buboes are much relieved by ice bags, which have also a good effect in circumscribing the infiltrations. Other applications, such as belladonna and poulteries, at times prove useful; when pus forms the bubo must be opened.

**Boston Medical and Surgical Journal.**

**July 24, 1913.**

**The Wassermann Reaction in Its Application to Medicine.**—W. P. Lucas says that the general usefulness of this reaction is being more and more recognized in cases of syphilis without clinical manifestations. He thinks it would be a wise precaution for insurance companies to have all questionable cases tested in this manner for their own protection, but admits that there are difficulties in carrying out such measures. The importance of the reaction is manifest in forensic medicine, and it is being used in civil as well as penal cases. The argument that a man is syphilitic can be made plausible to a judge much more easily by the fact that he has a specific reaction than by psychiatric explanations. As regards eugeneses, it seems very probable to him that this reaction will be used as an aid in deciding the question of marriageability, and that, to the present generally accepted rule, which demands treatment over a certain period of years before marriage, will be added the requirement of a negative Wassermann reaction. The therapeutic test for the presence of syphilis is of doubtful value, and is being replaced more and more by this more accurate laboratory test, which saves much valuable time and enables us to institute proper and thorough treatment when needed. Such a test is of great value in easing the minds of patients who are possessed by the idea that they have syphilis, as repeated negative tests are usually convincing and banish uncertainty.

**The End Results of Excision of the Knee for Tuberculosis with and without the Use of Bone Plates.**—Robert B. Osgood gives the following table of end results in twenty-eight consecutive cases; fourteen with and fourteen without bone clamps or plates:

<table>
<thead>
<tr>
<th>Type of Excision</th>
<th>Number of Cases</th>
</tr>
</thead>
<tbody>
<tr>
<td>Without Bone Plates</td>
<td>14</td>
</tr>
<tr>
<td>With Bone Plates</td>
<td>14</td>
</tr>
</tbody>
</table>

- **Subsequent amputation:** 3 (2 amputated later), 1
- **Subsequent reexcisions for nonunion or disease:** 2, 0
- **Persistence of pain several months after operation:** 5, 1
- **Apparent firm union in one month:** 6, 0
- **Firm union in two months:** 2, 6
- **Eventual firm union, but requiring three months or more:** 6, 3
- **No record of eventual union:** 6, 2
- **Subsequent removal of material used to hold bone ends together:** 3 amputated, 0 not amputated, 3 amputated case
- **Wire removed from both cases in which it was used:** 0, 3

**April 28, 1913**

**Congenital Abnormalities.**—H. W. J. says that congenital abnormalities are due to the manner in which the embryo is formed. The malformations are classified as follows:

- **Gross Malformations:** 7
- **Abnormalities of the Heart:** 3
- **Abnormalities of the Nervous System:** 2
- **Abnormalities of the Genito-Urinary System:** 1
- **Abnormalities of the Gastro-Intestinal System:** 1
- **Abnormalities of the Respiratory System:** 1
- **Abnormalities of the Skin:** 1
- **Abnormalities of the Bones:** 1
- **Abnormalities of the Muscles:** 1
- **Abnormalities of the Nails:** 1
- **Abnormalities of the Teeth:** 1
- **Abnormalities of the Ears:** 1
- **Abnormalities of the Eyes:** 1
- **Abnormalities of the Tongue:** 1

**April 21, 1913**

**The Hemorrhagic Diathesis of Thrombosis.**—A. C. Baer describes the hemorrhagic diathesis of thrombosis, which is a condition characterized by the occurrence of hemorrhages in various tissues, often so extensive as to cause death. The condition is due to a primary disturbance of the circulation, which may be caused by a variety of factors, including trauma, infection, and certain metabolic disorders. The diagnosis is made by a combination of clinical and laboratory tests, and the treatment depends on the underlying cause. The condition is often associated with an increased risk of thrombosis, which can be managed with anticoagulant therapy. The prognosis is generally poor, and the condition is often fatal.
Tumor of the Hypophysis in a Case of Acromegaly, by Dr. Julius Grinker.—See this Journal for July 5th, p. 47.

The Histopathology of Pompolyx.—From the study of a number of cases of pompolyx, which was first described, as a form of dyshidrosis, by Tilbury Fox, who believed that the condition was essentially characterized by the retention in the follicles of the skin of sweat, rapidly and freely excreted, Richard L. Sutton concludes that the pathological changes in this affection are confined almost wholly to the prickle cell layer, only a slight perivascular infiltration being present in the derma. The coil glands are not involved, and, at bottom, the condition is very probably a neurosis, the direct exciting cause being a toxin other than locally microbical in origin. Four of the nine patients whose cases are reported were treated with pilocarpine hydrochloride by the mouth, without appreciable results, and five with potassium iodide. Two of the latter received, in addition, two doses of pilocarpine each, hypodermatically.

Use of Palatine Mucous Membrane Flaps in Ankylosis of the Jaw Due to Cicatricial Formations in the Cheek.—John B. Murphy describes two cases in which this procedure was adopted with very satisfactory results. In the first case the flap was removed from the hard and soft palate, and consisted of mucosa and submucosa. It was pedicled and tongue shaped, and was swung outward so as to cover the denuded bony surface of the upper jaw formed when the jaws were chiseled apart. In the second case there were employed two tongue shaped flaps, one from the floor of the mouth and the other from the hard palate.

Creeping Eruption.—Gustave L. Rudell reports two cases of this rare affection, in the second of which he succeeded in recovering the larva producing the lesion. Previously only two had reported recovering the larva. In the first case the eruption completely disappeared under the use of ten per cent. chrysalarin ointment.

Etiology and Significance of Pericolic Membrane, by Dr. David Cheever.—See this Journal for July 5th, p. 37.

The Part Played by Functional Disorders in the Pathology of the Stomach.—Jacob Kaufmann expresses the conviction that the further study of diseases of the digestive organs, particularly in the earlier stages of their development, will demonstrate that the inborn or acquired disposition to irritative disorders of the stomach is often a very important and causative element. It was the use of the stomach tube which, for the first time, furnished a reliable method of studying gastric function and its disturbances. The findings of gastric analysis became well established facts, and provided a firm basis for a new pathology, a pathology of function. It is one thing to report findings, however, and another to interpret them, and it was in the interpretation of the newly established disorders of function that grave errors were and still are made. Through a one sided consideration, the importance of the functional disorder was greatly overestimated, and the grave mistake was committed of designating each derangement of function as an independent disorder, a disease per se. To make the error still more palpable, all these individual functional disorders were described as so many different types of gastric nerves. The undue emphasis thus given to disorders of function proved very confusing and misleading, and sometimes caused the overshadowing of the anatomical lesions by the functional disturbances with which they were associated. It required much work to correct such faulty conceptions, but it is gratifying to know that this is now thoroughly accomplished, and, while it is still justly held that functional disorders may be of independent character, it is generally understood that as a rule they are symptoms of disease, and that they are associated either with pathological conditions of the stomach, or other organ, or are manifestations of systemic derangements. Although errors in interpretation of the functional disturbances have been well recognized by clinical observers, they have been forcibly demonstrated by abdominal operations. But the pendulum has swung too far, and at present we see a pronounced tendency to understate the importance of the functional disorder or to discredit it altogether. In current literature the significance of the anatomical lesion is so strongly emphasized that it completely overshadows this. The author calls attention not only to the diagnostical value of the functional disorder, but also to the more important question as to how far the functional disorder acts as a causative factor. At present there is very little inclination to accept disorders of gastric function in any way as causative factors; they are usually considered as mere symptoms of diseases. Yet a critical observer who is not swayed by the prevailing trend of the day cannot fail to recognize that functional disturbances may play a very decided rôle as causative factors.

Internal Hemorrhages: Can We Control Them? by Dr. Frank Billings.—See this Journal for July 5, p. 49.

Two Cases of Circulatory Disturbance of the Brain, by Dr. C. Eugene Riggs and Dr. E. M. Hammes.—See this Journal for July 5, p. 47.

Clinical Significance of the Cerebrospinal Fluid in Nervous and Mental Diseases.—Morris J. Karpas first emphasizes some of the more important facts regarding the anatomy, physiology, and chemistry of the fluid. He next describes the various laboratory methods employed in its examination, and the clinical aspects of the subject, such as the indications and contraindications for lumbar puncture and the methods of performing it. Finally, he takes up individually the content of the cerebrospinal fluid in numerous forms of nervous and mental disease and in the secondary stages of syphilis.

Diuretic Drugs in Acute Experimental Nephritis, by Dr. Henry A. Christian.—See this Journal for July 5, p. 40.

Therapeutic Possibilities of Transfusion, by Dr. Bertram M. Bernheim.—See this Journal for July 5, p. 39.

Nonsurgical Treatment of Cirrhosis of the Liver, by Dr. N. S. Davis, Jr.—See this Journal for July 5, p. 50.
MEDICAL RECORD.
July 26, 1913.

Is Appendicitis Ever Catarrhal?—F. A. Palmer says that the caption catarrhal appendicitis is one found in all classifications of disease of the appendix, and is used to designate clinically those patients who show only slight but long continued or persistently recurring symptoms. Clinically the meaning of this term is clear and may suffice, but when the cases come to be classified upon the basis of the pathological condition present we find the widest divergences of opinion and description. In view of the predominance of lymphoid elements in the appendix, and the types of inflammation usually found upon microscopical examination of appendices, it is the author's opinion that the primary inflammation of the appendix is lymphoid, rather than catarrhal. From his studies on the subject the following conclusions seem warranted: 1. The gross appearance of the appendix is never a sufficient criterion of the severity of the pathological condition present. 2. Absolutely no idea of the nature or severity of the inflammation can be formed from the clinical symptoms. 3. Appendicitis may run its course through perforation and subsequent healing without symptoms which will admit of its recognition, or, indeed, severe symptoms of any kind. 4. The clinical condition designated as catarrhal appendicitis does not have a catarrhal inflammation of the appendicular mucosa as a pathological basis, and is, therefore, a misnomer which is dangerously misleading to the general profession. 5. No catarrhal inflammation, truly speaking, has ever been described as a pathological finding in appendicitis. For all these reasons the term should be definitely abandoned. Lastly, appendicitis is much more frequent than is usually assumed or than is indicated by our present means of diagnosis. The mortality of this disease is still large, and the only measure which offers any prospect of immediate reduction of this mortality is early operation upon all recognizable cases.

The Beneficial Effect of Duodenal Alimentation in Cirrhosis of the Liver.—Max Einhorn says that if we consider the intimate connection of the liver with the digestive apparatus, we have reason to expect that the rest given to the stomach by means of duodenal alimentation may have some bearing upon its neighboring organ, the liver. If the liver is diseased, its function of working up the portal blood and making it fit for the vena cava is slackened. What now happens is either the entrance of faulty metabolic products into the circulation or, if the supervision of the liver is still efficient but slow, an accumulation of blood in the liver, i.e., this organ becomes unable to work up all the blood flowing in during the process of digestion. Thus it becomes temporarily swollen. In some instances both factors coexist. In cirrhosis this difficulty in functioning is always present. In duodenal alimentation the upper part of the digestive system is not working, and is kept at rest. The venous circulation there is not very active; the portal vein is thus freed of part of its blood supply, and the entire work of the liver is made easier. Duodenal alimentation was applied in six cases of beginning cirrhosis. During this in all the six patients (five of whom had gastric ulcer) the liver became markedly smaller. In four the result was lasting; in one, the liver began to grow larger a few days after the termination of the feeding; and in one patient, with pure cirrhosis and dilated heart, the liver quickly resumed its original proportions. In this last case the influence of the procedure was very marked, but not lasting. The author concludes that the cirrhosis of the liver and allied conditions accompanied principally by swelling of the hepatic tissues form a field in which duodenal alimentation may be applied apparently to great advantage.

The Diagnosis and Prognosis of Duodenal Ulcer.—In the observation of some two hundred cases, by J. T. Pilcher, the history of an uncomplicated duodenal ulcer has in the great majority of them elicited four preeminent factors: 1. The chronicity of the complaint; 2, the periodicity of the exacerbations of epigastric distress; 3, the occurrence of pain of a peculiar character (burning or gnawing) with precise time of onset (between two and one half and four hours after eating); 4, the control of this discomfort by the ingestion of food or alkalies. In his experience, cases properly chosen for medical or surgical treatment appear to have remained fairly comfortable, and he feels justified in saying that the prognosis in the great majority of cases is good.

Treatment of Progressive Cases of Pulmonary Tuberculosis.—Mary E. Lapham believes that the recognition of the progressive nature of a case, far from releasing the physician from responsibility, adds another burden, that of deciding what must be done, and when. He must first of all be able to recognize when a patient is unable to make his own fight, and then come to his relief; first, by attempting an artificial pneumothorax, and, if this fails, then by resecting the ribs. The reported results from these procedures have been most encouraging.

AMERICAN JOURNAL OF OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN.
July, 1913.

A Study of the Induction and Augmentation of Labor Pains.—Welz, in discussing the various theories as to what terminates pregnancy agrees with von der Weide, who holds that the inception of parturition is caused by an anaphylactic action of proteid substances from the fetus to the mother. The author considers the fetus as a separate organism whose nourishment is received only by osmosis and dialysis through the placenta. As a result of fetal activities proteins gain entrance into the maternal circulation. As the fetus approaches complete development the result is that the proteid is altered in such a way as to free a poisonous group which is capable of producing an anaphylactic shock whose effects are centred in the uterus, which is most sensitive to the effects of this protein toxin. The results of the author's experiments, and those of others, indicate that the injection of fetal serum acts as a stimulus to the induction of labor. In the use of this material the danger of an anaphylactic shock must be kept in mind. Welz also mentions the results obtained by the injection of pituitary extract in causing uterine contractions.
Conservatism in Gynecology.—Taylor takes up the subject under the three headings of tubes, ovaries, and uterus. His teaching is that we want to relieve the patient’s discomfort, but we do not wish to destroy any function it is possible to save. In dealing with inflammatory conditions of the tube the author’s idea is to preserve as much as possible. Concerning the ovaries, however, he believes that when they are the seat of an inflammation it is better to remove them than to save them, even in a comparatively young person. If the patient is past forty the removal of the ovaries has little direct influence on the nervous system. In regard to the uterus, there is little value in leaving it if the tubes and ovaries have been removed. The greatest opportunity for conservative work is in the treatment of fibroids, whether or not a myomectomy may be performed.

The Treatment of Sterility by Intrauterine Stems.—Rawls discusses the advantages and dangers of this method, and concludes that in sterility it gives as good results as the cutting operations, causes less invalidism, and is no more liable to sequelæ. It is applicable to all cases of anteflexion with abnormal cervix, except in extreme pathological anteflexion and extreme shortening of the anterior vaginal wall.

Spinal Anesthesia. A Case of Acute Appendicitis Operated on Four Days after Labor.— Jacobson reports a successful case in which spinal anesthesia was selected on account of the pulmonary condition of the patient.

The Famous Case of Mary Toft, the Pretended Rabbit Breeder of Godalming.—Cumston gives a very interesting account of this person, who, according to Mr. St. André, anatomist to the King, had given birth to seventeen rabbits. As an example of the credulity of the times, 1726, this case is indeed remarkable.

Medicinal Treatment of Summer Diarrhea.—Carr considers the objects in the treatment of summer diarrhoea as fourfold: To aid nature in her efforts to clear the stomach and intestine of the material that is the source of the irritation; to lessen the effect of gastroenteric irritability and general toxemia; to sustain strength and aid digestive processes; and to restore the normal functions of the intestine. The drugs that are recommended are castor oil and calomel, salol and bismuth, stimulants, as alcohol, camphor, caffeine, and strychnine, and agents to increase digestive power. Opium not to be used except when the frequent stools exhaust the child and interfere with a rational routine of management.

AMERICAN MEDICINE.
May, 1892.

The Passing of Tuberculosis.—Sir R. W. Philip invites attention to actual facts—the extraordinary development of pathological knowledge and of therapeutic and preventive procedure within recent years—and the consideration of whether these are certainly leading. Those who have lived through the gloomy periods of pessimism are best able to appreciate the extent of the optimism implied in “the passing of tuberculosis.” Tuberculosis has this in common with syphilis that there is a definite, if not always traceable, point of entrance of the invading organism. It differs from syphilis in the fact that the disturbance at the point of inoculation is generally slight and more transient. At whatever point inoculation has occurred, the further course consists, for the most part, in a general spread by way of the lymphatic system; and it is impossible to emphasize this too strongly. The author is strongly convinced that it is at the lymphatic stage that tuberculosis ought to be opposed, and that, when thus opposed, its further spread in the system is readily prevented. The chief danger in tuberculosis does not lie in the anatomical changes produced—whether in the lung or elsewhere; the significant factor in the process is the systemic intoxication, the outcome of the bacillary invasion. The tuberculous toxines would seem to act especially on neuromuscular structures, and the results of such action are generally in evidence long before cough or expectoration, or other indication of local lesion, is forthcoming. The chief error in the past has lain in too exclusive attention to the local manifestation, wherever presented, while too little has been paid to the bacillary invasion as such. In this sense, the common separation between so called medical and surgical tuberculosis is artificial and unscientific. The tuberculized patient should be viewed pathologically and therapeutically from the same kind of standpoint as the syphilitic one; each being the subject of a definite systemic infection which is insidious, tenacious, and protean in manifestation. If the pathological position presented be conceded, the first great move toward effective treatment will be the adoption of a complete revision of the standard and methods of diagnosis. The earliest manifestations of tuberculosis must be better defined and studied. Especially does the lymphatic stage require accentuation; and fine multiple enlargement of glands must be searched for. Symptoms of neuromuscular intoxication must be viewed with care, and of special significance is general muscular dystrophy. In respect of visceral (more particularly pulmonary) lesions, there is room for much greater refinement of diagnosis than is usually practised or taught. Bacteriological evidence must not be restricted to the demonstration of the tubercle bacillus; if we wait for the actual appearance of the bacilli in discharges, we wait much too long. The more recent tuberculin tests have contributed greatly to case and exactness of diagnosis, and there are signs that we are within no great distance of more satisfactory serological tests. Accumulating experience at the tuberculosis dispensary led the author many years ago to institute what he termed the “march past” of the infected households, and the fact—eviduced by this systematic examination led to the conclusion that tuberculosis was far commoner among children than had been supposed. If the principle of the “march past” were universally carried out, not merely at the tuberculosis dispensary, but likewise in general practice, tuberculosis in its grosser forms would disappear. Tuberculosis has been shown to be most tractable, when taken in hand sufficiently early and sufficiently firmly. In speaking of direct therapeutics the author states that he has employed tuberculin continuously since 1890.
with results proving it to be a specific remedy of great value, provided it is used early enough and properly administered long enough.

**Treatment of Hemorrhage in Typhoid Fever.**

—Hardee Johnston deprecates the application of the ice bag, raising the foot of the bed, and the use of opium. The treatment which he has found most satisfactory is irrigation with three or four gallons of cold water, allowed to flow slowly into and out of the rectum. Were the patient in severe shock from the hemorrhage, he would prefer to use warm water. As a rule, however, the first hemorrhage is not sufficient in amount to cause much shock; though, of course, the ulcer might be so located that the first hemorrhage would be the only one, and cause death.

**INTERSTATE MEDICAL JOURNAL.**

*June, 1913.*

**Kinetic Theory of Surgical Shock and Anoci Association.**—G. W. Crile says that while we have long known that disturbance of any part of the vasomotor mechanism might cause shock, it remained for an extended series of laboratory experiments and clinical observations to teach us that the vasomotor and other disturbances were intermediary between the cause and the effect. The key to the final cause of shock was found in a study of the phylogenetic history, not of the vasomotor system alone, but of the whole motor mechanism. As a result of a train of reasoning and certain researches, he formulated what he calls his “kinetic theory of surgical shock.” This assumes a number of points, among which are the following: That traumatic stimuli of sufficient number and intensity lead inevitably to exhaustion and death; and that when the expenditure of energy caused by emotional stimuli cannot take its normal course and produce motor activity, the condition reacts upon itself; the stimulation thus being automatically increased, and the resultant expenditure of potential energy proportionately active. The final condition in either of these two instances is designated shock. In solving the question, Why is not the administration of an inhalation anesthetic a sufficient preventive of shock? the author made a series of experiments upon animals which showed conclusively that if the connection between the brain and the traumatized part could be broken, the brain cells would be protected from damage; and he found that this could be accomplished by a thorough infiltration of the tissues to be traumatized with a local anesthetic. By the use of a nonoxidizing general anesthetic, nitrous oxide, and of a local anesthetic, novocaine, he achieved the thorough protection of the brain cells from danger during the course of the operation itself. As psychic strain may be as active as actual trauma in producing shock, the search was made for a drug or drugs which would do away with the preoperative dread of the approaching ordeal, and it was found that morphine and scopolamin, in physiological doses, prevent psychic shock. If one could now discover a procedure which would diminish or eliminate postoperative suffering, the protective cycle would be complete; and by continued experimentation he found that this end could be secured by an infiltration of the parts surrounding the line of suture with quinine and urea hydrochloride. By these means there has been developed a new operative principle which he terms anoci association. To carry it out requires a careful and expensive technic. A detailed description of this technic in abdominal and goitre operations is given; indicating the universal application of the principle. The proof of a surgical principle, Crile states, is found in the clinical results of its employment. In its adoption at the Lakeside Hospital, Cleveland, it has been found that there is no longer need of a postoperative recovery room; that the work of the nurse has been greatly minimized; that the clinical aspect, both in and out of the operating room, has been altered.

**Priciples of Treatment in Malnutrition and Atrophy of Infants.**—John Foote believes that if we accept the findings of recent investigators, we must regard atrophy as a condition in which foods containing even normal quantities of sugar and fat are not well absorbed, and are likely to produce intolerance. Rational treatment would therefore suggest a food poor in sugar and fat, but relatively high in its proportion of proteins, to compensate in a measure for the reduction of these energizing elements—one not unlike skimmed milk, excepting that the latter contains its normal proportion of sugar. In the author’s opinion no food fulfills the conditions so well as albumen milk or albumen buttermilk. Used in twenty-four hour quantities of from one to three ounces to each pound of the infant’s weight, these foods frequently tide babies over the danger of collapse and restore tolerance for other foods. Small amounts should be fed at first, and gradually increased, especially if vomiting be present; and, unless the infant is less than a month old, the interval between feedings should be at least three hours. When the twenty-four ounce quantity has been increased to two or three ounces to the pound of body weight, sugar may be added (preferably a malt sugar) until an ounce or an ounce and a half is being given; but until the infant has begun to gain steadily it is unsafe to give the larger quantity. As early as possible (but not earlier) these soured milk foods should be replaced by mixtures of skimmed milk and, later, whole milk. Cream mixtures are not usually well borne at this time. Months of patient work are often required to bring these infants up to a normal metabolical condition. More of the intestine accompanies the atrophic condition, so that constipation is apt to result from the increased amount of food. This may be corrected by an increase in malt extract or the use of suppositories. In severe cases collapse may complicate matters, especially in very hot weather; and rapid loss of weight, sunken fontanelles, weak pulse, and a very low pulse, with pinched, ashed features, are danger signals. Whiskey, strychnine by hypodermic injection, salt solution, and external heat are all useful in this complication.

**The Treatment of Sciatica.**—G. A. Young advises that the primary treatment of an acute attack should be diaphoretic. A full hot bath, followed by hot drinks and frequently repeated doses of tincture of aconite, with complete rest, often cut short the attack. Aspirin, or full doses of the salicylates may
also be used, and the bowels should be thoroughly flushed, preferably with salines, for several days. Prolonged hot applications, dry or moist, are of great service. The use of the arc lamp often produces striking results. After the first diaphoretic measures the author has found daily hypodermatic injections of from 1/10 to 1/6 grain of pilocarpine nitrate valuable in sciatica, as well as in interstitial neuritis. In the more chronic cases he gives the pilocarpine in the evening, and after the injection he has the patient sweat between blankets, and then rubbed down and placed in a warm bed. Galvanism should be used after the diaphoretic measures have failed to remove the pain. The diet should be restricted and should be suitable to the "uric acid diathesis." Water should be given freely, and may also be used in the form of high normal salt colonic flushings. The treatment of chronic sciatica, apart from the correction of adjacent local disease and the systemic intoxication present, may be summed up under three heads: baths (both thermal and light), massage, and the injection treatment. Perhaps the treatment most in the professional eye at present is that by the Lange-Schlesser method, which consists in the injection of 100 c. c. of 0.1 per cent. of beta eucaine in physiological salt solution into the perineural sheath of the sciatic nerve. Various modifications of this have been suggested and employed.

JOURNAL OF MEDICAL RESEARCH.
July, 1913.

The Complement Content of the Blood in Malignant Disease.—Ordway and Kellert conducted hemolytic experiments with thirty serums, from twenty-seven cases of moderately and markedly advanced carcinoma. They conclude that the hemolytic complement of the blood serum in different varieties and stages of human cancer is in the majority of cases relatively constant, the amount being practically the same as that found in health and in persons suffering with certain other diseases.

Factors in the Production and Growth of Tumor Metastases.—Tyzzer takes up in his article some very important points concerning surgery in malignant disease: Will the growth of the secondary masses be accelerated by the removal of the primary tumors, and will life thereby be shortened or prolonged? Also, do the procedures followed in the course of physical examinations or surgical operations increase or diminish the incidence of metastases? The results obtained in Tyzzer's investigation find practical application in the management of tumor patients. They are of such character that every physician should realize the irreparable harm which may result from the manipulation of malignant tumors in their early development. Although the present observations are made on a tumor in which dissemination usually takes place by way of the blood stream, it seems reasonable to expect similar results with human tumors which become disseminated by way of the lymphatics. The course of procedure to which the patient is frequently subjected—the palpation of the mass in question in repeated physical examinations, the violent scrubbing often employed in preparing the field of operation—is almost identical with that which Tyzzer employed for the experimental production of metastases. It would be of advantage to the patient if each questionable tumor of the breast, for example, could be regarded as a high explosive, the least manipulation of which should be absolutely avoided, both prior to and during the operation. It is not improbable that by this means metastasis and extension beyond the field of operation could be prevented and the proportion of cases cured by operation increased. From the point of view of metastasis, it would appear from these results much less serious to cut into a tumor than to exert pressure upon it, although the effect of the distribution of tumor tissue throughout an extensive operation is quite generally understood.

MONTHLY CYCLOPEDIA AND MEDICAL BULLETIN.
June, 1913.

Scarlet Red in the Treatment of Gastric and Duodenal Ulcer.—Julius Friedenwald and J. F. Leitz, reporting upon thirty-seven cases of ulcer in which scarlet red was employed, assert that this agent is a useful adjuvant in the treatment of peptic ulcer. While it cannot replace the usual forms of treatment (Leube and Lenhardt), when administered in conjunction with them, it often renders the cure more complete. As a help in ambulatory cases it is of great service, its effect being apparently even more favorable than that obtained from bismuth. Its use need not in any way interfere with the giving of other remedies, such as the alkalies or belladonna, when indicated. It is best administered in doses of fifteen grains, three or four times daily, before meals. It may, however, be given in much larger doses. No toxic effect was observed during its employment in over one hundred patients.

Pulmonary Syphilis Complicating Pulmonary Tuberculosis.—F. N. Robinson mentions as evidences of the coexistence of these two conditions: (1) Marked dyspnea in a case of lung tuberculosis only of short duration; (2) primary affection of the larynx, the picture upon local examination being that of syphilis, not tuberculosis; and (3) abundant expectoration of mucous or slightly mucopurulent material. Upon physical examination, the most striking feature is the extensive pulmonary involvement, with otherwise an apparently excellent state of nutrition. A "rustling" murmur over the junction of the middle and lower lobes and "burr" or "snoring" heard over the bronchi are also characteristic. The sputum shows but a small number of tubercle bacilli and occasionally nonmotile spirocha; there is a great disproportion between the number of poly-nuclear and of mononuclear cells. The Wassermann reaction is, of course, also available for diagnosis. In the treatment, the use of mercury should be limited to mild inunctions, administered only at intervals. Iodine is indicated above all. The author gives tincture of iodine in doses of from two to five drops, three times daily, increased up to ten or twenty drops, in a wineglassful of milk. He has seen favorable results in two cases from the administration of salvarsan. As for the prognosis, when tuberculosis attacks a syphilitic in the primary and secondary periods the prognosis is grave, while in the tertiary period it is somewhat better. When
a tuberculous patient becomes infected with syphilis, the prognosis is bad in proportion to the period of previous existence of the tuberculosis.

OPHTHALMIC RECORD.
July, 1919.

A Case of Spring Catarrh: A Pathological Report.—Hanford McKee found the following histological changes in tissue removed from a case of vernal catarrh: 1. The epithelium was thickened to three or four times its natural depth; 2. It dipped into the tissue beneath, giving the well known epitheliomalike picture; 3. beneath the epithetlum were foci of degeneration. There was also fragmentation of the connective tissue, with collections of basic staining débris, leucocytes, and lymphoid and plasma cells. Ingrowths of new capillaries were noted; 4. the deeper parts, too, were infiltrated with plasma cells and eosinophiles. There was a marked preponderance of the latter, which were often seen between the epithelial cells; 5. Plasma cells were also found in follicliclike groups, but these were very different from the typical lymph follicle. The histological picture was therefore one of a chronic inflammatory process, with a great deal of infiltration, necrosis, and destruction of fibrous tissue, followed by repair and down growth of the epithelium. As a result of the changes in the underlying tissue, the epithelium had become secondarily diseased, had proliferated, and had extended into the deeper parts.

Proceedings of Societies.

MEETING OF THE AMERICAN THERAPEUTIC SOCIETY.

_Held at Washington, D. C., May 5 and 6, 1913._

(Continued from page 254.)

Recent Improvements in the Quinine Treatment of Lobar and Lobular Pneumonia.—Dr. S. Solis-Cohen, of Philadelphia, recalled that the death rate of pneumonia for forty years, according to good authority, had ranged between 20 and 22 per cent, and in the last decade, between 30 and 40 per cent. Both the mortality and the number of cases were increasing. Hence it was deemed worth while to continue direct personal attention to the comparatively favorable result, that is to say a mortality of from 9 to 12 per cent, that attended a special method of treatment. During the last few years the roof wards at Jefferson Hospital and the galleries at Blochley had offered improved facilities for obtaining that constant supply of fresh air which was an integral part of the method, and the more favorable showing for this period might be attributed in part to that factor. Apart from fresh air, dependence had been placed upon the following measures: First, the effective use of the very soluble double hydrochloride of quinine and urea in 50 per cent. solution by intramuscular injection. Secondly, the hypodermic injection of collodion hydrochloride solution or an extract of the posterior lobe of the pituitary body, for the maintenance of blood pressure. Third, in cases of prolonged fever, delayed resolution, or tardy convalescence, the injection of bacterines (pneumococcus or "mixed" vaccines, personal or stock). Doctor Pottenger inquired as to the length of the time required for complete resolution in the average case of pneumonia. We were inclined to think that the process went on rapidly and was completed in a short time, but his experience in the examination of tuberculous subjects had led him to believe that the time required for resolution was much longer than was commonly supposed. He also asked what was meant by a "large dose" of digitals. He had found 25 drops of the tincture sufficient in most cases. The shortness of the attack was a noticeable feature. The chart showed the death of one patient, in whose case was due to bacterial invasion and the proper vaccine could be used there should be a shortening in the length of the disease and in the time required for resolution. It regarded one man made well and another man another, with any method of treatment. Success was chiefly due to the observance of minuette. It was the same with pulmonary tuberculosis. One man obtained an indifferent result, and another obtained a good result from practically the same treatment. The treatment was the treatment of the patient, not of the disease. Individualization and the observance of minuette were the most important points making for success.

Dr. Kolpinski said that in the formula presented by him the corrosive substance did not seem to act as a poison. He had given more than the usual grains of the medicine in twenty-four hours without injurious effect. Little cough and scanty expectoration signified a severe case of pneumonia, whereas much coughing and profuse expectoration indicated quick recovery. Of course the kind of case and the presence of complications should also be taken into consideration.

Doctor Morris inquired whether, if the mortality from pneumonia was increasing from year to year, a relation could not be traced between this and the lessened facilities of the body to combat the disease? The grip bacillus. He also asked whether there was any particular significance in the painting of the skin with iodine before giving the injections of quinine and urea—whether this had any special chemotactic effect of the injection. He believed that every physician had his own private method of treating pneu monia but that the agents and measures employed did not make much difference so long as they were given with care.

Dr. S. Solis-Cohen, in closing, said that the element of confidence was undoubtedly of the highest importance. As to tetanus, his experience with the injection had lasted over thirty years. It began in Doctor Bartholow's clinic in the treatment of chronic malaria. He had not seen a case of tetanus in over 5,000, possibly 10,000, injections. He had met with just four instances of sloughing, and three of them occurred before the present technic was instituted in 1886. Since then he had seen one case, and that had followed an injection given by a nurse. He had always given instructions that the injections be to be given by the internes, but the injection was overlooked in this case. In his opinion the sloughing was due to a corrosive action upon the skin and subcutaneous tissues, but as the capillaries were covered with rubber and made the injection through it, thoroughly emptying the syringe to prevent any drops of the preparation from falling upon the skin. The puncture was sealed with collodion or iodiform collodion. According to his experience, the only objection to the injection was that it was broken, not upon the unbroken skin. Gripe infection and the consequent lowering of resistance had undoubtedly played a part in the increased mortality and prevalence of pneumonia. So far as mortality goes, statistics were all value. It was possible, in a large measure, to exclude the secondary cases. There was no doubt but that the mortality from pneumonia had increased rapidly. He believed that this was partly due to the wave of therapeutic optimism that had swept through. Many of the patients might have recovered if they had been under the care of some one with confidence in his own treatment. Doctor Pottenger's suggestion that pneumonia not infre mits more or less of an individual effect. He believed that the bacterines would prove of value in meeting this condition. Under the treatment outlined in the paper defervescence usually occurs by lysis rather than by crisis. He still observed crisis in mild cases of pneumonia in which the specific is not interfered with by the absence of cinchonism. It would appear that the pneumonia poison and the quinine counteracted or neutralized each other. This tended to prevent cardiovascular failure, one of the most dangerous possibilities.
in the course of the disease. Each case, however, should be treated upon its own merits. There was no one treatment for all, and in individualization lay the key to success.

Pulmonary Syphilis, with Report of a Case Promptly Responding to Specific Treatment.—This paper, by Dr. Arthur E. Roussel, of Philadelphia, will appear in the Journal.

In discussion Dr. Thomas E. Satterthwaite, of New York, said that at various times he had tried to bring up a discussion of this subject. At first he could hardly get anyone interested in pulmonary diseases of the lungs. The cases were thought to be instances of pulmonary tuberculosis. The pathological findings, however, were very instructive—particularly the white radiations running out from the gumma. The disease lay concealed in the primary diagnosis. Once a diagnosis had been made, the gummatas in the lungs and all the symptoms rapidly disappeared under appropriate treatment, and this was an important diagnostic point. A positive blood reaction was a great help. The discovery of the germ would demonstrate that cases of pulmonary syphilis are more frequent than is generally supposed.

Doctor Potterton spoke of the difficulty of making a correct diagnosis. The absence of tubercle bacilli from the sputum is not conclusive of the diagnosis. Some tuberculosis patients but rarely presented bacilli in the sputum. In case of one patient who had been in the sanatorium for fifteen months, the bacilli were detected in the sputum only twice. Their presence could easily be overlooked in such cases. The examinations were made frequently and very carefully.

Doctor Osborne spoke of the value of the iodiodes from a diagnostic standpoint. They were ordinarily contraindicated in pulmonary tuberculosis. If, however, there were no tubercle bacilli in the sputum they could be given, and if afterward no bacilli were found, the diagnosis was clear.

Doctor Evans said that there were other affections than pulmonary tuberculosis that should be taken into consideration in making diagnosis. Doctor Morris said that there was still another affection that should not be overlooked in making the differential diagnosis. He related a case which turned out to be a case of anthraxymyosis.

Doctor SATTERTHWAITE said that in the early stages it was almost impossible to differentiate between pulmonary tuberculosis and syphilis of the bronchial glands.

Doctor Potterton had not found potassium iodide helpful. He had tried it in a great many cases and had often found it beneficial.

Doctor Osborne said that in incipient cases, according to his experience, the iodiode was liable to stir up the pulmonary condition and make matters worse. He recommended potassium iodide as a preventive. The potassium iodide was followed by a lighting up of the symptoms and a change for the worse. In chronic cases the effect was something similar, but it enabled the patient to resist the symptoms.

Climatic Conditions in California and Their Influence in the Treatment of Tuberculosis.—Dr. George Herbert Evans, of San Francisco, after describing the climatic conditions of various parts of California in respect to the treatment of tuberculosis, entered a protest against the custom of sending tubercular patients away from home without provision for constant medical guidance. He hoped that medical men everywhere would come to realize that with tuberculosis, as well as with other diseases, in particular, one such case in which the patient is capable of being treated properly, that medical care should be the first consideration in sending patients from home.

The selection of a suitable climate, based upon a careful consideration of the needs of the individual case; a proper correlation of rest and exercise; proper attention to the nutritional requirements of the patient; and all of the factors dealt with in the treatment of tuberculosis, no theoretical argument, however, as to climate could weigh for a moment against the abundant testimony of successful treatment by men trained in the healing of the patients, regardless of the locality in which they lived.

What Does Treatment Offer to the Advanced Tuberculous Patient.—Dr. Francis M. Potterton, of Los Angeles, emphasized the necessity for early diagnosis and treatment. Failure to make an early diagnosis was sometimes the fault of the patient and sometimes of the physician. Too often the physician regarded lightly the request of the patient for an examination of the lungs. This is a failure on the part of the physician to present an early diagnosis, as in old unrecognized cases in which the symptoms suddenly became acute. While the early tubercule was comparatively easy to heal, the disease became progressively more difficult to heal as soon as the symptoms disappeared. In the clinical features in different stages, the essayist dealt with treatment including the advantages of sanatorium treatment for chronic cases. An important factor was a careful regimen, suited to the individual, and carried out under proper medical supervision. Under these conditions recovery could be expected to take place soon. A case was not hopeless so long as the patient could digest and assimilate food and the heart was capable of performing its functions.

Dr. Spencer D. Davies, of Albany, heartily agreed that the physical council was the only thing that gave his patients recovery. He was very particular about his patients receiving individual medical attention. It was not sufficient to send these patients to California, or Colorado, or elsewhere. If one had to choose between care without climate and climate without care, he would do well to choose care without climate. Each patient should have individual treatment.

Doctor Osborne expressed appreciation of the paper. He agreed with Doctor Potterton as to the value of tuberculosis sanatoria for the patient recovering from pneumonia, typhoid, and other diseases and even those suffering from slight debility should be carefully watched. In tuberculosis one should never give up. Recovery had occurred in cases that seemed about to give up.

Dr. J. W. Chappell, of Washington, D. C., agreed with this. The physician could learn a lesson from the very persistence with which these patients held on to life. They lived along from year to year and some of them managed to live longer, even when left alone. Sometimes he had noted that one lung of an apparently healthy man, whom he was examining, was inactive. Inquiry disclosed that twenty years before, the man had had "lung trouble," but had recovered without treatment. Tubercular patients who were believed to be quiescent had been known to die. It was impossible to see that each one received careful personal medical attention. As to incipient cases, whenever he had a patient who was running down steadily without any known cause he strongly suspected tuberculosis.

Doctor Kinyoun said that the management of tuberculosis was a nice problem. It took two to make a bargain. The physician could make the diagnosis and prescribe the treatment, but it rested with the patient to carry it out. Any attempt to send the patient to a sanatorium to restore the patient to his former physical condition fell short; for example, one that only enabled the patient to live and do light work in the place to which he had been sent, but not to return home, was a mere apology for a sanatorium. All cases were not suitable for treatment away from home.

Doctor Potterton said that many patients did better away from home than at home. The beneficial effects of change of surroundings, freedom from care and worry. The influence of optimistic people, a suitable climate, all were well recognized. Changing and moving around from place to place was fatal.

The Medical Treatment of Cholecystitis.—Dr. H. B. Anderson, of Toronto, Canada, admitted that while surgical procedure was frequently the best, and often the only means offering a chance of relief, its advocacy based on certainty of cure and assurance of nonrecurrence was unwarranted. The main object of treatment was the removal of the gallstones. To this end, the patient was usually subjected to an operation, the removal of gallstones. This not infrequently occurred under nonoperative treatment, especially in early and mild cases and particularly after first attacks before serious local damage had been done by the infection. Medical treatment was inadvisable in those cases in which the patient's physical condition did not warrant operation, and in the numerous cases in which operation was refused. It should be employed in many cases as a preliminary to operation in order to allow the acute infection to subside as far as possible. It should be carried out in all cases after operation, to prevent reinfection and recurrence, if possible. He never advised strongly against operation in any case unless an operation was definitely contraindicated because of the patient's physical condition; but, after explaining the possibility of failure and
that operation might eventually be required, he did not hesitate in early or mild cases, or after first attacks, to give medical treatment a thorough trial, and this course in many instances gave excellent results.

Doctor Roessz, however, whereas gallstone patients were usually first seen and treated by the physician and by him often referred to the surgeon, the surgeon but rarely after operation turned the patient over to medical treatment. Intercurrent treatment was to do practice was very different from that obtaining abroad, especially in Germany, where it was the custom for the surgeon to turn the patient over to the physician after operation for medical treatment and care. Instances had occurred where我也需要手术 had been attended with undesirable results.

Doctor STEWART spoke of the treatment of cholecystitis by bacterial vaccines. Whether or not the treatment was effective was merely a question.

Orthotherapy, the Power Which Correct Posture, Organic Adjustments and Mobility Exert upon Health and Its Recovery.—Dr. JOHN MADISON TAYLOR, of Philadelphia, stated that deformities caused by posture and costume impaired the health in many ways. Physical deformities of this class were treated but when the objectives, were too often regarded as mere matters of course, as distinguishing characteristics, and dismissed as of no moment. A conspicuous stoop, a lateral twist, a sagging waist, high shoulders or hollow chest, bent knees and such unstable postures are evidence of some kind of faulty taste, or as finger marks of fate. They were often deliberately perpetuated, even exaggerated, and too frequently imitated. A grave significance was added when it was shown that these deformations were in truth exaggerations of developmental faults, inducing degenerative changes in nerve centres or conduction paths; morbid slackness in tissues, central defects, impaired nutrition in important structures, causing compensation and resulting in all tendencies to produce yet worse conditions in vital structures.

Treatment of Splanchnoptosis, with Report of Cases.—Dr. Elmer B. Freeman, of Baltimore, emphasized that congenital cases should be recognized in early childhood. Exercises might tend to increase the capacity of the abdomen and develop strong abdominal muscles might decrease the number of severe cases. Cases without deformations, or with loose adhesions, could be relieved and made comfortable by proper medical treatment. Cases with a large separation and marked constriction of any portion of the gastrointestinal tract, with symptoms of chronic obstruction, required surgical intervention. The medical treatment referred to above had for its object the improvement of nutrition, an increase of digestive power and correction of all tendency of gastric disturbance, and the removal of constipation. Forced feeding, rest in bed, and the use of a suitable corset might be required. The author preferred the corset recommended by Doctor Gallant some years ago.

Dr. A. ERNEST GALLANT, of New York, said that in many cases the organs could be adequately supported and the downward pressure counteracted. The corset referred to by Doctor Freeman, to his mind, best met these indications. He had used it since 1893. The average corset on the market to-day failed to furnish an adequate support, or if it did furnish a support it acted upon an erroneous principle. Under them all at the bottom in front was a space that allowed sagging of the abdominal contents. The patient would be induced to keep her body in such a position that the organs would be in such a position that they would drop down with this. The best way was to put the patient on her back, raise her hips, and allow the organs to flow back, using massage if necessary, and then to fit the corset. This would be done up so that there would be no tendency to falling down of the abdominal contents. He believed that his corset met these requirements. It did not permit of any sagging, whether the patient was standing, sitting, or lying down. It put a sheath around the organs and kept them up. He had had experience with the sensation of "dragging" that so many women experience. The cause of this sensation was the sagging of the unsupported organs upon the whole system of attaching ligaments and checking it from falling down. If it were supported held up not only the abdominal viscera; but the thoracic viscera as well.

If the epigastrium was hollow as compared with the hypogastrum the chances were that there was displacement. Each organ might not sag much but the downward pull of all together caused the discomfort. The relief afforded by a properly adjusted corset was demonstrated by the change that came over these patients when they were able to remain in a sitting or lying position. Some of them had to go to bed while it was being repaired.

Doctor ZUEBLIN, of Baltimore, referred particularly to the etiology. Heredity was undoubtedly of importance. Some of the patients came from a race whose nature predisposed to visceral displacement. There might be impairment of the muscular tone, for example, or tendency to stomach trouble. The patients were especially liable to infection owing to lowered resistance. There was a hyperchondriasis and nervous character of the patient.
ment. Some cases did very well with rest in bed and atropine, bismuth, or one of the other remedies commonly employed. The treatment was either medical or surgical. The patients who did not respond to medical treatment should be treated surgically. (To be continued.)

Book Reviews.

[We publish full lists of books received, but we acknowledge no obligation for review. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

The first two chapters of this book are devoted to general surgical methods and the routine steps of a correct and adequate form of the operation. The last chapter, of course, is surgical. The .balance to the operations on the eyeball and its appendages. The writers give this as the plan they have followed: "First, be described in a group of operations we have discussed the disease for the relief of which they are intended, and have given clear indications for the selection of the proper procedure in any given case. A detailed description of the steps of each operation follows, with a list of all the instruments required. After this are complications, that may occur at the time of operation or later, are taken up together with the postoperative care of the patient." The book is admirably illustrated and is a thoroughly practical work. The personal element stands out in the relation between the Indian and the European methods of operating for cataract and glaucoma, due to the positions taken by the operators, are beautifully brought out. The directions are clear and precise; so far as such directions can go toward the making of a surgeon the authors are excellent. But why should Saemisch's keratotomy be described in full when it has been superseded by the better procedures of pars plana and cataractophthalmology? In speaking of canthoplastic Agnew's method is referred to several times and is described as a step in Kuhnt's operation, but Agnew's cantholysis is far more efficient than simple canthotomy when it is desired to relieve the pressure of the upper lid upon the eyeball and deserves a separate paragraph. The omission of such operations as the extraction of a capsule by the Sir Astley Cooper method and the preliminary capsulotomy suggested by Smith of Norwich leaves us to infer simply that they have not been practised by the writers. The only quite slip we have noticed is the advice to make a free and deep incision in anthrax of the lid; this we believe to be absolutely contradicted, for the less the site of the lesion is interfered with in anthrax, the less is the danger of a systemic infection. Quite a number of operations are described which are seen more commonly in the European clinics, while others not infrequent in America are omitted, but on the whole the purpose of the book, to be a practical work on the surgery of the eye, of use to every one interested in ophthalmology, is well carried out.

This volume is a very timely addition to our knowledge of the surgery of the pancreas, spleen, and mesentery, which surgeons have to a great degree left to the field of physicians. Disorders of the spleen and mesentery have undergone considerable change in recent years, and advantage is of the knowledge of the surgeons to afford to the student.

Cabot's diagnosis differs from other books on the subject in that he omits the description of tests and clinical data relevant to the author at least, scheme of no advantage or with which he is not familiar. For instance, because of his lack of acquaintance with cystoscopy, ophthalmoscopy, and laryngoscopy, he fails to describe them, without, however, devaluing their value as clinical resources. His aim, however, is to give those features of the disease of which he has found valuable, precisely as a therapist recommends only those remedies which he has found helpful. This attitude renders the diagnostic data which he describes in detail all the more valuable in that they are treated with a degree of care and lucidity seldom met with in books on diagnosis, which, too often, are rather careless compilations of the useful and useless; thus serving to fatigue rather than instruct the reader.

This little book, in pamphlet form, on poor paper, badly printed, miserably illustrated, is a good translation of the Binet-Simon papers on their system of ascertaining the mental status of children, now well known in the United States. The translator, Dr. Clara Harrison Town, has, however, given considerable change to the text, and we hope that the cheap makeup—which is quite inexcusable, seeing that one dollar is charged for the book—will not militate against its success.

Although the writer rightly holds that no mere book can take the place of the personal instruction in the wards, the fact remains that the student requires at least a carefully coordinated summary of the knowledge he is to see applied at the bedside if he is to profit seriously from the instruction it affords. The book before us aims to supply a method in parco of the means of investigating the student needs for this purpose, viz., the various methods of investigation and the significance of symptoms and their relative value as signs to detect each condition present. The text is prepared with much care and obviously by a master hand. It lacks illustrations, which are always so elucidative in diagnosis, and we hope that the author will further enhance the value of his excellent work by filling this omission in the next edition.

That Whitta's Dictionary of Treatment should have reached its fifth edition and a sale of twenty-eight thou- sand copies sufficiently emphasizes the fact that com- mendment is hardly necessary. Judging from the dedica- tion to American authors and others, the value of the book but its excellence has doubtless caused it to be used ex- tensively by the profession at large. The fifth edition

This small book is intended to furnish the general practitioner with a summary of the practical facts regarding therapeutic agents, indicating those diseases in which its various forms are most generally useful. The author adds a few facts based on his own experience, the therapeutic indications advocated being all capable of duplication by any painstaking observer with equal success. On the whole, this little book is a very satisfactory one; it is not overloaded with the physics of electricity and in clear concise language gives the practitioner precisely what he should know to judge cases. An excellent glossary, which derives the text of any asperities, even for the merest tyro, closes the volume.

This book has for its main purpose to protect insurance companies, manufacturers, etc., against imposture, and indirectly to protect the worthy sick and victims of industrial accidents. As the author states, many deserving cases do not receive proper consideration because unworthy persons have had expended upon them the sympathy and help which are the legitimate right of the true sufferer. Many litigations would be avoided, we might add, if the malingerer did not cause most applicants to be suspected of having an interest in the outcome. It is the duty of the physician to identify the actual wrongdoer, each organ being studied in turn, constitutes the bulk of the work, which is certainly a meritorious one and entitled to a large circulation.

This is an able attempt to place on a more stable foundation what knowledge is available on apparent death as differentiated from real death. Many examples of burial before life was extinct are related—all garnished from authoritative sources—the need of a scientific study of the whole question being emphasized. The general subjects taken up are: Latent biological activity; the autonomy of organs and functions as vital entities; latent life in superior organisms; the stages of moribundity; the persistence of life notwithstanding apparent death; the physiopathology of death; later appearance in the newly born fetus; phenomena of residual life; the signs of death, and, as the closing feature, a critical appendix of the various means, so far as proposed, to avoid premature burial. The work is a valuable one and well worthy of translation.

The author's name is sufficient to indicate that the book is one of considerable importance, and that the evidence has not been misplaced. The writer takes up the question from all points and gives it a very complete presentation. Considerable emphasis is laid upon the various ways of making a careful examination of the heart, particularly the microscopic and electrographic methods which is now daily employed. The disturbances in other organs are reviewed, and much attention is given to the underlying principles in the treatment of cardiac disturbances. Somewhat more than half the book is devoted to lesions of the heart muscle resulting from certain definite conditions. The publication can be recommended as a valuable addition to the literature on the subject.

In this monograph of ninety-eight pages Doctor Haffkine divides the subject into three portions: One dealing with the technique of preparation of an anticholera vaccine; the second with the immunization of man against cholera; the third, with the anticholera vaccine and its devitalization. The material originally used was a virus in live condition, brought by successive cultivations in guinea-pigs to a uniform and stable degree of virulence. This, known as vaccine, has been improved so that its toxic and immunizing effects are still observable in the vaccine when it is devitalized by delicate chemical or physical processes. If it should still retain sufficient potency for immunizing man against natural cholera there would be a great advantage in replacing the anticholera vaccine by the protective inoculation. Doctor Haffkine, therefore, believes that the devitalized vaccine II should be subjected to a careful study in cholera epidemics. The article is a valuable one in that it reports the results of extensive and prolonged researches. The book is of interest to all who are interested in the subject.
L., Assistant Surgeon. Directed to proceed to Ellis Island, N. Y., and report to the chief medical officer for duty.

**Appointments.**

Dr. Joseph Bolten, Dr. Robert C. Derivaux, Dr. John S. Ruoff, Dr. Tully J. Liddell, Dr. Harry C. Cody, and Dr. Walter L. Treadway commissioned assistant surgeons in the Public Health Service July 22, 1913.

**Boards Convened.**

Board of commissioned medical officers convened to meet at the bureau to examine and grade the papers of applicants for appointment as assistant surgeon. Detail for the board: Assistant Surgeon General W. J. Pettus, chairman; Assistant Surgeon General L. E. Cofer, recorder.

Board of commissioned medical officers convened to meet at the Marine Hospital, Detroit, Mich., on Monday, August 4, 1913, at 10 o'clock a.m., for the physical examination of applicants for appointment as assistant surgeons and for the presentation of questions for the written examination. Detail for the board: Senior Surgeon H. W. Austin, chairman; Surgeon M. J. White, recorder.

Four assistant surgeons were detailed to meet July 7, 1913, for the examination of applicants for appointment as assistant surgeons, reconvened to meet August 4, 1913, for the same purpose.

Assistant Surgeon Liston Pain detailed as recorder of the board of medical officers convened to meet at the marine hospital, Chelsea, Mass., August 4, 1913, for the physical examination of applicants for appointment as assistant surgeons and for the presentation of questions for the written examination, vice Surgeon H. W. Wiekes, relieved.

Board of medical officers convened to meet at Washington, D. C., for the reexamination of four children of Morris Hoffman, an alien resident of Washington. Detail for the board: Surgeon Joseph Goldberger, chairman; Surgeon J. W. Schereschewsky, recorder.

**United States Army Intelligence:**

**Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Army for the week ending August 2, 1913:**

**Baker, David, Major, Medical Corps.** Detached from duty at Fort McPherson, Ga., and ordered to Camp Perry, Ohio, accompanying troops. **Bradley, A. E., Lieutenant, Colonel, Medical Corps.** Ordered to make inspection of the following coast defenses: Long Island Sound, Nantucket Bar, Bar Harbor, New Bedford, New London, and Portland. **Davis, William T., Captain, Medical Corps.** Resignation accepted to take effect November 15, 1913.

**Doerr, C. E., Captain, Medical Corps.** Detached from duty at Fort Thomas, and ordered to Camp Perry, Ohio, accompanying troops. **Doshier, Julius A., First Lieutenant, Medical Reserve Corps.** Ordered to report on August 9th for temporary duty. **Lyster, Theodore C., Major, Medical Corps.** Upon arrival in the United States, in compliance with orders heretofore issued, with further orders to Fort Monroe, Va., will proceed to Fort McPherson, Ga., on August 9th for temporary duty. **Kennedy, J. S., First Lieutenant, Medical Reserve Corps.** Ordered to report on August 9th for temporary duty.

**McKinney, G. L., Captain, Medical Corps.** Granted leave of absence for twenty days, about August 29th.

**McConkey, James, Major, Medical Corps.** Granted leave of absence, effective from present duties.

**Mills, Raymond W., First Lieutenant, Medical Corps.** Resignation accepted, to take effect August 20, 1913; granted leave of absence to and including August 20, 1913.

**Porter, Ralph S., Captain, Medical Corps.** On arrival in the United States from Alaska will proceed to Fort Sheridan, Ill., for duty.

**Roberson, Horace M., First Lieutenant, Medical Corps.** On arrival in the United States from Alaska, will proceed to Fort Terry, N. Y., for duty. **Smith, Herbert A., First Lieutenant, Medical Reserve Corps.** Ordered to active duty and will proceed to Fort Port Royal, S. C., for duty during the illness of Major Sanford H. Wadhams, Medical Corps, upon whose return to duty Lieutenant Smith will return to his home and upon arrival there will stand relieved from active duty in the Medical Reserve Corps. **Stallings, M. C., Captain, Medical Corps.** Ordered from duty at Madison Barracks and ordered to Camp Perry, Ohio, accompanying troops. **Thode, E. F., First Lieutenant, Medical Reserve Corps.** Ordered to Fort Ontario for temporary duty. **Wadhams, S. H., Major, Medical Corps.** Granted leave of absence for eighteen days, to terminate not later than August 14th, by Special Orders 136, Eastern Department. **Wickline, William A., Captain, Medical Corps.** Granted leave of absence for one month, effective on or about August 15, 1913.

**Williamson, L. P., First Lieutenant, Medical Corps.** Will report at 9 a.m., on August 18, 1913, to Colonel Charles Richard, Medical Corps, president of the examining board at the Army Medical Museum Building, D.C., for commission to proceed to sea and report for duty, on completion thereof, to return to proper station.

**United States Navy Intelligence:**

**Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Navy for the week ending August 2, 1913:**

**Camerer, C. B., Assistant Surgeon.** Detached from temporary duty at Washington, D. C., and ordered home to await orders. **McMulin, J. J. A., Passed Assistant Surgeon.** Detached from duty as assistant surgeon from March 28, 1913. **Smith, H. W., Passed Assistant Surgeon.** Detached from the Montana and ordered to the Montgomery.

**Deaths.**

**Married.**

**Johnson—Haymore.**—In Ashville, N. C., on Wednesday, July 16th, Dr. Harry McIngell Johnson, of St Louis, Mo., and Mrs. Haymore. **Thompson—Evans.**—In Westmoreland, Md., on Thursday, July 22d, Dr. W. L. Thompson of Milwaukee, and Miss Hazel L. Reeves.

**Wheat—Flint.**—In Manhester, N. H., on Saturday, July 19th, Dr. Arthur F. Wheat and Miss Rachel Flint.

**Died.**

**Bell.**—In Baltimore, Md., on Wednesday, July 23d, Dr. Samuel Bell. **Corson.**—In Plymouth Meeting, Pa., on Thursday, July 24th, Dr. J. K. Corson, aged seventy-seven years.

**Dowd.**—In Waltham, Mass., on Saturday, July 26th, Dr. Edward F. Dowd, aged thirty-eight years.

**Duhigg.**—In Bath Beach, N. Y., on Tuesday, July 29th, Dr. Bernard A. Duhigg, aged forty-one years.

**Evans.**—In Cheswold, Del., on Sunday, July 20th, Dr. Owen Herbert Evans, aged forty-nine years.

**Harris.**—In South Bend, Ind., on Tuesday, July 22d, Dr. Robert Harris, aged ninety years.

**McLenaenth.**—In Willsboro, N. Y., on Wednesday, July 23d, Dr. Bernard A. McLenaenth, aged fifty-eight years.

**Linn.**—In Oconee, Ill., on Sunday, July 27th, Dr. W. T. Linn, aged one hundred and eight years.

**McLenaenth.**—In Willsboro, N. Y., on Wednesday, July 23d, Dr. Bernard A. McLenaenth, aged fifty-eight years.

**Reynard.**—In Stanford, Conn., on Wednesday, July 30th, Dr. Walter E. Reynard. **Smith.**—In Washington, D. C., on Wednesday, July 23d, Dr. Thomas C. Smith, aged seventy-one years.

**Straungh.**—In Snow Hill, Md., on Wednesday, July 24th, Dr. William J. Straungh, aged forty-nine years.

**Swift.**—In Boston, Mass., on Tuesday, July 29th, Dr. John Baker Swift, aged fifty-nine years.

**Taylor.**—In Hartford, Conn., on Sunday, July 30th, Dr. Charles J. Taylor, aged sixty years.

**Westbrook.**—In Bensenville, Ill., on Saturday, July 14th, Dr. George R. Westbrook, of Brooklyn, N. Y. **White.**—In Glyndon, Md., on Wednesday, July 23d, Dr. John W. White, aged seventy-five years.

**Wunder.**—In Sabillasville, Md., on Sunday, July 20th, Dr. Joseph C. Wunder, of Baltimore, Md.
The prevention of deafness

By G. Hudson-Masken, M.D.

Philadelphia

Some one has said that the duty of the physician is threefold: (1) to prevent; (2) to cure; and (3) to alleviate. Applying this principle to the subject of deafness, it would seem that we have reversed the order of the three duties, and our efforts have been (1) to alleviate; (2) to cure; and (3) to prevent. Some one has also well said that the time to cure deafness is before it begins, a seemingly paradoxical statement, and one implying that the affection when thoroughly established is incurable. The prevention of deafness, therefore, is a subject toward which the attention of the modern otological world is rapidly turning, and one which the progressive general practitioner of medicine can no longer ignore.

One of the difficulties arising in any discussion of this subject is to make a satisfactory etiological classification of it. The assigned causes for deafness are so numerous and varied that it is difficult even to group them. In a recent report issued by the United States Bureau of the Census, in which 80,287 cases of so-called deaf mutism were returned, over 300 different causes were assigned for the condition. The classification usually made in dealing with the subject, namely, congenital and acquired deafness, is not altogether satisfactory, because it is difficult to differentiate between the two conditions, and many of the recognized causal factors are common to both congenital and acquired deafness. Similar objections arise, however, in any classification of the subject, but the one that appears to be the most satisfactory for my purpose is the following:

**Classification of deafness.**

- Inherited deafness
  - Gross physical anomalies, congenital—Total deafness, deaf mutism
  - Minor physical anomalies—congenital
  - Primary, origin. in the ear
- Diseases of the ear
  - Secondary, resulting from systemic diseases
- Injuries to the ear
  - Falls
  - Blow
  - Explosions
  - Burns
  - Scalds

The great objection to this classification is the fact that it is extremely difficult to entirely eliminate heredity as a causal factor even in many of the so-called acquired cases.

Deafness, let it be remembered, is not a disease, but the result of certain physical conditions which are either inherited or acquired. The inherited conditions which result in deafness are for the most part congenital, and they appear either as gross physical anomalies of the organs of hearing, such as productive of the profound deafness of deaf mutism, or as minor physical anomalies not necessarily confined to the ear, but extending to other portions of the organism as well, and productive either of the partial deafness of childhood or of the somewhat indefinite state known as the "tendency" or "predisposition" to become deaf in later life.

The acquired conditions which result in deafness, on the other hand, are more pathological in character, and they arise (1) from diseases of the ear, either primary or secondary, and (2) from injuries to the ear, which are usually traumatic in origin. Primary diseases of the ear are those which originate in the ear itself, and secondary diseases of the ear those which result from general systemic diseases, such as the exanthemata and other infectious fever diseases, including syphilis and tuberculosis.

1. Inherited deafness

Time was when the existence of inherited deafness could reasonably be questioned, but that time has now passed. Recent investigations have shown conclusively that heredity is the great predominating factor in the causation of so-called congenital deafness, and there is good reason to suppose that much of that usually classified as acquired deafness is also of hereditary origin. The United States Bureau of the Census, working in conjunction with the Volta Bureau in Washington, and at the suggestion of Dr. Alexander Graham Bell, has been engaged for many years in the collection of data and the tabulation of statistics relating to the educationally deaf, and the result is a book by Dr. Edward Allen Fay, entitled, *Marriages of the Deaf in America*. Doctor Fay's book is replete with carefully tabulated statistics, based upon a personal correspondence with thousands of deaf persons whose names and addresses were furnished by the enumerators of the eleventh census, and I have summarized the conclusions as follows:

Marriages of the deaf are far more common in our country than in Europe, and during the past century they have increased enormously, their increase being proportionate to, and simultaneous with, the increase of schools for the deaf. Marriages of the deaf with the deaf are more numerous than those with hearing persons, and they are only a
little less productive than ordinary marriages. Marriages of the deaf are exceedingly liable to result in deaf offspring. Marriages of the congenitally deaf are more liable to result in deaf offspring than are those of the adventitiously deaf. Deaf persons having deaf relatives, however they are married, and hearing persons having deaf relatives and married to the deaf, are very liable to have deaf offspring, the proportion of marriages resulting in deaf offspring and the proportion of deaf children born from therefrom being almost invariably highest where both of the partners had deaf relatives, and next where one of them had deaf relatives, and the other had not, and least where neither had deaf relatives. The marriages of the deaf most liable to result in deaf offspring are the consanguineous marriages. Out of thirty-one such marriages, fourteen, or 45.1 per cent., resulted in deaf offspring, and of the 100 children born from these marriages thirty, or thirty per cent., were deaf.

The investigations of which this is a summary have been confined hitherto to the congenitally deaf, or to those acquiring deafness so early in life as to place them for all practical purposes in the congenital class, but I am informed that the plan is about to be enlarged so as to include in the future a study of all classes of deaf persons, whatever may be the character or cause of the affection. This will be a great improvement, for it will serve to clear up some mooted points in connection with the etiology of what has been called sporadic and acquired deafness. I have long been of the opinion that heredity is an important factor in the causation of these forms of deafness, as it is in the educational form, although perhaps this theory may not be so easily proved.

The sporadic cases of congenital deafness are generally supposed to be due to such diseases and conditions as syphilis, tuberculosis, alcoholism, insanity, idiocy, and the like, and in as much as these diseases and conditions have themselves been shown to be largely transmissible, I see no reason why the conditions giving rise to such forms of congenital deafness may not be regarded as having an hereditary origin. Moreover, by far the greater number of cases of so called acquired deafness may be similarly explained. They are acquired because inherited physical anomalies have made their appearance, and in some cases perhaps unavoidable, and thus they may be regarded as indirectly inherited.

True, hereditary deafness has been limited in our classifications to that of those showing a clear family history of deafness, either in direct or collateral branches, and this limitation has been made because of the mistake of supposing that deafness is the particular thing inherited, whereas, as I have said, what are really inherited are the physical anomalies which result in deafness. These physical anomalies may be transmitted by those having other forms of defectiveness in the same manner as they are transmitted by those having a family history of deafness. Thus, even the seemingly acquired deafness of adult life, or so called catarachal deafness, may be regarded as hereditary in so far as the particular physical and systemic conditions which cause it, such as rheumatism and gout, are hereditary or transmissible, and, reasoning thus, we may be justified in the conclusion that all deafness, with the exception of that of traumatic origin, is in part at least due to some hereditary taint. Whether or not I am right in this supposition, time and further study will reveal, but we now know beyond any doubt that heredity is an important and increasing factor in that most serious and distressing of all forms of deafness, namely, the congenital form, and the question arises, What are we going to do about it? What prophylactic remedy is indicated?

The procedure that naturally suggests itself is embodied in the phrase, "a stricter application of the principles of eugenics" to the subject of deafness. And what does this mean? It means, among other things, a more determined effort on our part to check the transmission from parents to offspring of the particular physical anomalies which result in deafness. And how can this be done? It can be done most effectively, of course, by rendering those who transmit such anomalies physically incapable of reproduction.

In a paper read before the American Academy of Medicine in 1900, I advocated sterilization for the prevention of crime, pauperism, and mental deficiency, and I am pleased to note that the procedure is now being sanctioned by law and practiced in Indiana, California, Oregon, and Connecticut. Moreover, there was recently appointed in the State of New York a special committee on procreation, composed of three physicians. We shall watch with interest the action of this committee, and it is a matter of congratulation, I think, that it should be composed of physicians who are in a position to know the facts which should warrant any action on the subject. Who knows but that the time will come when the practice of sterilization, drastic as it now seems to us, will be adopted even for the prevention of hereditary deafness.

Another effective measure, and one less radical, would be the denial of the marriage license to those who transmit the physical anomalies which result in deafness. This measure should be considered at once. Surely, the "strong arm of the State" should be used to regulate such marriages of the deaf as are known to result in a high proportion of deaf offspring, and this is especially true in view of the fact that the State is doing all that it can to make these marriages possible by bringing the deaf together in large institutions and increasing their economic efficiency. In other words, our efforts to ameliorate the conditions of the deaf have tended to foster their increase. In the first decade of the last century the proportion of marriages of the deaf to the whole number of marriages during the century was only 0.02 per cent., and it increased with the increase of the number of schools during each subsequent decade until in the ninth it was 22.7 per cent. This fact suggests, as another possible preventive measure, a change in our methods of education for the deaf. Instead of bringing them together in large residential schools, of which we now have about 150, with upward of 13,000 pupils, I would recommend special day school instruction, which would not only obviate the state of propinquity which is so likely to result in marriage, but would have the additional advantage of keeping the deaf in closer association with hearing people during their educational career.
These are somewhat radical measures for the prevention of deafness, but they are measures which should be discussed and which sooner or later must receive serious consideration. We are face to face with conditions which have led close students of the subject, like Dr. Alexander G. Bell, to fear the possible "formation of a deaf variety of the human species," and thus they seem to call for drastic measures. In the meantime we can do much by a campaign of education, in which the truth may be disseminated, and the facts in the case given the widest possible publicity. Those of us who know should discourage as much as possible the marriage of the deaf which are liable to result in deaf offspring. I use the word discourage because the times do not yet seem to be ripe for absolute legal prevention. We may, forsooth, control the breeding of our cattle, but our modern notions with reference to personal liberty, especially as it relates to the question of marriage, are such as to interfere very materially with the application of eugenic principles. I am a believer in "personal liberty," but when it interferes with the happiness and usefulness of unborn generations of fellow persons, I think it should be at least curtailed, and if necessary prohibited by legal measures.

2. Acquired Deafness.

When the measures which I have suggested for the prevention of inherited deafness shall have been more generally adopted, we shall have fewer of the conditions or anomalies which make the acquisition of deafness so easy and in some instances almost unavoidable. When we shall have eliminated heredity as a factor in the causation of deafness, the prevention of acquired deafness will be greatly facilitated. As it is, I am of the opinion that acquired deafness is preventable in the great majority of instances, and I am thus optimistic, not because I have any new remedies to exploit, but because I have so much confidence in the old ones when applied in a timely and rightful manner.

The way to prevent acquired deafness is to prevent the development of those pathological conditions of which it is a result. Primary diseases of the ear proper are exceedingly rare. Most of the so-called primary ear diseases arise in the nasopharynx, and their secondary effects upon the ear are largely preventable by a stricter application of well-known remedial principles. Our modern surgical treatment of adenoids is probably the best procedure yet devised for the prevention of acquired deafness, but it could be made far more effective by doing the operation earlier and by making it more general and more thorough. Many ears are still being sacrificed to tardy and careless surgery in this region. As someone has said, we are in the habit of calling the fire engine after the house has been burned, and I may add that the coming of the fire engine often renders the house uninhabitable. Our operations are performed in too many instances for the sole purpose of relieving some immediate symptom, and with too little consideration for the saving of an important function. I have called attention to this point in connection with the tonsil operation. Just as the surgeon has not done his full duty in a tonsil operation until he has improved the speech and voice, so has he not done his full duty in other operations in this region until he has eliminated the acting and predisposing causes of deafness.

Moreover, as a further preventive measure, I would advocate a thorough and careful examination of the ears of very young children and an earlier treatment of the conditions which have been found to result in deafness. This work should not be left entirely to the general practitioner, but it should be done in part at least by the skilled otologist. Another important measure is that suggested by Dr. Sohier Bryant, namely, a periodic examination of all ears similar to that practised with reference to the eyes, in order to detect and enable us to treat threatening conditions. Early examinations and treatment are especially indicated in those cases showing a family history of deafness.

The exanthemata and other infectious fevers of childhood are common causes of acquired deafness, and their prevention, of course, should be regarded as among the possibilities of the near future. Notwithstanding the attitude of certain foolish sentimentalists toward vaccination, smallpox has been almost entirely eliminated as a factor in the causation of deafness, and typhoid fever bids fair to have a similar fate. May we not hope that scarlet fever, measles, whooping cough, mumps, and cerebrospinal meningitis may soon follow in their wake? In the meantime, no effort should be spared to mitigate the awful effects of these diseases upon the ears of children. This is a work that calls for a fuller cooperation of the general practitioner with the specialist, and it is no credit to either that about twenty-five per cent. of all cases of acquired deafness should have their origin in these infectious diseases.

Interesting investigations are now being carried on across the water with reference to syphilis as an etiological factor in the causation of deafness. It has been shown that in the congenital form it may cause congenital deafness, and that it is an undoubted factor in the causation of so-called acquired deafness. In view of these facts, Dr. James Kerr Love suggests as preventive measures, making the pregnancies of syphilitics and all still births notifiable, in order that preventive measures of treatment may be promptly adopted. He calls attention also to the fact that our modern remedy, salvarsan, when given for the eye complications of congenital syphilis, has seemed to have the effect of actually impairing the hearing.

Finally, as has been well said, the prevention of deafness is the work of the eugenist, the hygienist, and the legislator. It is the function of the eugenist to see that children are well born, of the hygienist to see that the mother is cared for during pregnancy, and the child immediately thereafter, and it is the function of the legislator to enact such laws with reference to deafness as the eugenist and hygienist find to be desirable and practicable. Moreover, in these days of progressive medicine, the physician himself should be a eugenist, as well as a hygienist, and should take a leading part also in the adoption of the laws which make for health and happiness.

1627 Walnut Street.
THE IMPORTANCE OF SEROLOGICAL ANALYSES IN NEUROLOGY.

By D. M. Kaplan, M. D.,
New York,
Director of Laboratory, Neurological Institute.

The discovery of the cause of tuberculosis established for all time the importance of finding tubercle bacilli in the sputum. Routine clinical microscopy and chemi-try of the gastric and intestinal contents rendered gastroenterology an inestimable service, in furthering the diagnosis of the diseases of the digestive tract. A study of renal functions is useless without uranayes. The various hematological findings are essential in the diagnosis and treatment of a number of diseases which without such aid would prove very uncertain. It is just as important for the neurologist to be able to obtain laboratory corroboration in the making of a diagnosis in a case where syphilis is suspected. The etiology of many nervous diseases is obscure, and it is very desirable to be able to ascertain the presence or absence of a syphilitic factor (acquired or congenital) in an obscure neurological disorder. It is very natural that the spinal fluid, coming in contact with the nervous system as it does, should receive chemical and morphological constituents from these structures. When abnormal constituents are given off to the spinal fluid the importance of a laboratory analysis is established when it furnishes to the clinician the proof of such abnormality. Besides this there are other arguments why routine laboratory work is essential to neurology. Owing to the comparative difficulty in obtaining spinal fluids for clinical purposes, the analysis of this medium was resorted to very infrequently. The earliest attempts at withdrawing spinal fluid were made for therapeutic purposes, with the idea of relieving pressure. In 1886, Essex Wynter in England conceived the plan of performing an intraventricular puncture on an infant with tuberculous meningitis and effected the desired reduction of intracranial pressure. The following year he had under his care a case of purulent meningitis in a child whose fontanelles had closed. Being desirous of reducing the pressure in this case, and being unable to puncture the ventricles of the brain as in the former patient, this pioneer induced a surgeon to remove the lamine of the second lumbar vertebra and incise the dura to allow of the escape of the cerebrospinal fluid, and thus reduce the intracranial pressure. This was the first "lumbar puncture," and the idea was rapidly seized upon by other workers. The year 1891 saw the reports of four cases of tuberculous meningitis, in which paracentesis of the theca vertebralis was done as a therapeutic measure, and in one case, that of an infant thirteen months old, a Southey's tube was inserted between two lumbar spines and four ounces of fluid withdrawn. The result of this last experiment was unfortunate, for the little patient died after two hours. The name of Quincke is very rightly associated with lumbar punctures for therapeutic and diagnostic purposes. Quincke in his first publication in 1891 not only simplified the technic of the lumbar puncture, so as to bring it within the reach of the many, but also made studies upon the pressure of the spinal fluid in different states. His first puncture was performed under anesthesia, but he soon discarded this precaution.

Up to this time only the pressure of the spinal fluid had interested clinicians, but, following Quincke's work of making lumbar puncture not only a simple but a safe operation, many laboratory workers now began to investigate the physical and chemical properties of the fluid thus obtained. It was very natural for the physiological chemists to grasp eagerly this newly obtained body fluid for analysis. Early observers reported the finding of blood products in the fluid following brain hemorrhages. In 1901 Mott and Halliburton published the statement that nerve degeneration manifested itself by the presence of cholin in the spinal fluid. Further investigations along this line, however, showed that the method for the detection of cholin was of little value, as it proved to be not specific for cholin alone. but might be obtained in other substances normally present in the spinal fluid. Coriat, in 1904, continued this line of investigation and determined not only the cholin, but also the lactic acid content of the fluid, and established the nature of its copper reducing constituent. In regard to the latter substance Proflander found that the fluids of patients with tuberculous meningitis rarely reduced Fehling's solution, while those of acute cerebrospinal meningitis never did. Nissl again led us back to the subject of spinal fluid pressure, a subject upon which the last word has by no means been spoken, and he also introduced a qualitative test for the protein content of the fluid. This latter was a new point and one fraught with much diagnostic interest, as the amount of protein, so called globulin, was seen to vary in different conditions. Nissl's method entailed the use of Esbach's reagent and the centrifuge; soon attempts were made to simplify this method, all of which have depended upon the same procedure, i.e., precipitation. In Nonne's globulin test ammonium sulphate is used to obtain precipitation; depending upon the amount of precipitate obtained, the designation of "Phase I, II, III and IV" is used. Phase I represents the greatest excess, phase IV the least excess. Later, Noguchi applied the butyric acid precipitation test to the spinal fluid to determine the globulin excess, and still later Ross devised a ring test with ammonium sulphate for the same purpose. The writer has combined the last two methods and has thus introduced a method whereby the globulin excess in the spinal fluid may be ascertained with considerable accuracy. While the chemists were busy with spinal fluid the microscopists were not laggards. The presence of lymphocytes in the spinal fluid had long been noted, but it remained for Widal, Sicard, and Ravaut, in 1901, to attach diagnostic significance to this lymphocyte content. This was a great step in advance for neurological diagnosis, as it opened a wide door of approach to the clinician. These authors showed that there is a preponderance of lymphocytes in tuberculous meningitis, while in the purulent and epidemic forms the polynuclear elements are in excess. More important than this, they determined that in tabes and in general paralytic the number of mononuclear cells was
greater than normal. In investigating other nervous diseases the authors found no increase of cells in recent and old hemiplegias, in brain tumors, in alcoholism, in peripheral neuritis, in hysteria, and in two cases of anterior poliomyelitis. In 1902 Joffroy and Mercier studied the spinal fluid of the insane by means of this method. They found the cell count normal in ten cases of dementia praecox and in seventeen of alcoholic psychosis. In general paresis the cells were always in excess, and these authors believed that they could exclude this diagnosis where the cell content of the spinal fluid was normal. The method of Widal, Siaard, and Ravaut was cumbersome and tedious, as well as inaccurate. The number of cells was estimated by counting the cells observed on a smear after centrifugation. Investigators soon attempted to simplify the technic and to make it as ready of application as is blood examination. Kraemer used the ordinary Thoma-Weizs blood counting chamber, and in eleven cases of general paresis he found that the number of cells ranged between five and forty-five to each c. mm. Merzbacher considered fifteen cells to each c. mm. the upper limit for cells in normal fluids.

He found a cell increase in 100 per cent. of general paretics and that among these sixty-five per cent. showed globulin excess. According to Parkinson, the number of cells in the fluids of paretics tends to lessen in the stages of decline and to increase during the lucid intervals. Undoubtedly the best method of estimating the cells in the spinal fluid is that with the chamber devised by Fuchs and Ro-enthal. This chamber, which is larger than the Thoma-Weizs blood chamber, has the advantage of reducing errors to a minimum, this being the method used on fluids reported in this article.

The appearance in 1906 of the work of Wasser- mann, Neisser, and Bruck on the serodiagnostic reaction in syphilis opened a new field for spinal fluid research. This reaction, now so widely known as the Wassermann reaction, has been extensively studied by many workers, and while it is not accepted as specific, its practical utility is now above question. It was ascertained at a very early date that this serodiagnostic reaction need not necessarily be present in every patient who had come in contact with syphilis, and also, that there are diseases other than syphilis capable of giving this reaction. Boas and Hauge found it in scarlet fever, Bruck and Gessner in lepra, Kaplan in scleroderma and in certain jaundiced sera, Hartoch and Jakinoff in trypanosomiasis. From the very beginning attempts were made to produce an equally sensitive test of less complexity, chiefly by M. Stern, Bauer, Tchernougoff, von Dungern and Noguchi. Zeissler's "Auswertungs Methode" with serum, and later Hauptmann's application of the method to spinal fluids, were designed to make the test more sensitive. Working with sera from general paresis patients, Muirhead obtained seventy-six per cent. of positive Wassermann reactions. The most comprehensive exposition of the serology of nervous diseases is to be found in the work of Plaut and of Nonne. The former established a definite serological picture for cerebrospinal syphilis, finding a positive Wassermann reaction in the serum and a negative result in the spinal fluid in the majority of instances.

Hauptmann, with the use of his "Auswertungs Methode," obtained almost 100 per cent. of positive results, working with spinal fluids from patients suffering from cerebrospinal syphilis. This work and Nonne's article, appearing in the September, 1911, issue of the Deutsche Zeitschrift für Ver- senheilkunde, being in line with the work carried on by myself, will receive more detailed consideration. It is my opinion that the use of larger quantities of spinal fluid, as advocated by Hauptmann, may in some instances be responsible for a nonspecific inhibition. It is a well known fact that there are conditions other than lues capable of giving a positive Wassermann result; it seems to me that these nonspecific results could be reduced to a minimum if it were not for the fear that some serological workers possess of missing a positive Wassermann reaction on a syphilitic patient. Regardless of this, suspicion should be aroused when the laboratory begins to claim infallibility of methods and results. Of the forty-four cases analyzed by Hauptmann only two were admitted to have been benefited by previous therapy. The fact that about twenty per cent. of fluids were absolutely free from a pleocytosis did not seem to affect the value of the method in the least, although Hauptmann's chief, Nonne, strongly emphasized the importance of an increase in the cell content in fluids from all patients with true paralytic affections of the nervous system. (See above mentioned article, page 203.) In about four per cent. of this material Hauptmann was unable to obtain a positive result on the fluids. From the arguments that follow one carries away the impression that a negative Wassermann reaction was unexpected and undesirable. The attitude of the "Auswertungs Methode" advocate becomes apparent when the following statement is analyzed: "Not until larger quantities of fluid were utilized could a positive Wassermann reaction be obtained." The critically inclined worker is fully justified in asking what the factors were that prompted Hauptmann to look for a positive result and to make use of larger quantities of fluid in a given case. Evidently, the reason why a negative Wassermann result was not desirable was because the author possessed data suggestive of neurological lues. This will in a measure account for the positive Wassermann reactions obtained in some patients who undoubtedly had received sufficient treatment to negative the fluid serology, and will also explain why he did not in one instance find a serological picture similar to those described by Plaut. It is important to remember that cerebrospinal lues is invariably accompanied by a pleocytosis. A few exceptions are to be obtained in the endarteritic form of this disease and in those patients with general paresis who survived a very persistent and strenuous antiluetic treatment. Hauptmann entirely ignores the importance of a pleocytosis and on page 260 of his article states with considerable emphasis that "now we are enabled to detect syphilis of the nervous apparatus without the help of the other three tests (cell count, protein excess, serum Wassermann)".
Concerning the work of Nonne, who introduced the "Phase I" test, I would say that this method of estimating an excess of protein in the spinal fluid lacks a well defined end reaction. This makes the test largely a matter of personal interpretation, preventing other laboratory workers from comparing results. The frequently uncertain attitude of Nonne in reading end results is apparent from an analysis of the article previously mentioned, pages 283, 284, 251, 255, 272, and 275. The chief weakness of Nonne's contribution, however, lies in his noncritical acceptance of the results obtained by Hauptman. The clinician ought not to be puzzled by a positive result in a case of multiple sclerosis, nor should the laboratory worker attempt to explain or defend his result in such a case. If no clinical evidence of lues is obtainable it is to be taken for granted that the laboratory made a mistake. Some of Nonne's cases which gave a positive Wassermann reaction showed at the autopsy no luetic tissue changes. The question of posttherapeutic negativation was entirely overlooked by Nonne in accepting a positive Wassermann reaction in every case with signs of neurological syphilis.

My experience is based upon an analysis of over 3,000 spinal fluids and over 15,000 Wassermann tests, the material being chiefly neurological. In a previous report, in association with Dr. L. Casamajor, this material was arranged in three groups viz., the positive types, comprising the diseases of the nervous system caused by syphilis; the negative types, including the nonluetic nervous affections; and the types as altered by therapy. The last is practically a subclass of type one, as it deals with the serological changes produced by treating syphilis of the nervous system.

My conception of neurological serology can be seen from the following statements:

1. A nervous disease of syphilitic origin showing no increase in the cell content in the spinal fluid will as a rule show the absence of a positive Wassermann reaction in the fluid. Among the 3,000 spinal fluids that were sent to my laboratory 1,091 were from patients with syphilis of the nervous system. Among these 1,091 fluids, six exceptions to the stated rule were seen. Of these 1,091 fluids, six exceptions to the stated rule were seen. One general paretic who had received in the neighborhood of fifteen full doses of salvarsan intravenously showed an absence of cells and a positive Wassermann reaction in the fluid. The same was obtained in five cases of the endarteritic form of cerebrospinal syphilis.

2. With the above exceptions in view, it can be accepted that a positive Wassermann reaction in the spinal fluid is as a rule accompanied by a pleocytosis.

3. Untreated cerebrospinal lues of the meningitic and gummatous forms without a pleocytosis has never been observed by me, although negative Wassermann reactions in fluids from such patients were frequently encountered (Plaut type).

4. Some tabetics and a few cases of general paresis will show a negative serology throughout.

5. After proper treatment a positive serology may become entirely negative.

In my work on neurological serology the protein content was determined as described by me in various publications on the subject; the Fuchs-Rosenthal method was used in counting the cells; the Wassermann reaction was performed as practised by the Berlin school, except for the method of standardizing the amboceptor. Here normal serum and two units of inhibitory extract were used, together with the original hemolytic system. This procedure eliminated the possibility of using an amboceptor that was too weak to cope with the interfering qualities of normal serum and the antigen. The chief aim in the laboratory of the Neurological Institute is to eliminate as much as possible positive reports on nonluetic material; when a negative report on a syphilitic is obtained the clinical facts decide the diagnosis and therapy. Regardless of these precautions, it was impossible to eliminate errors to the extent of two tenths of one per cent. This occurred in the serum only; it never took place in the spinal fluid. In 316 spinal fluids the method of Hauptmann was resorted to, and the result gave one fluid positive where with the original procedure a weakly positive result was obtained. The patient suffered from tabes and showed thirty-seven lymphocytes to each c. mm. in the fluid. As will be pointed out in this communication, an abnormal serology may become entirely normal after appropriate therapy. It is an important fact that during the period of return to normal (negativation) the Wassermann reaction becomes negative in the spinal fluid before the cell count becomes entirely normal. Had this been observed by Nonne, less weight would have been placed on the positive Wassermann reaction in the fluid, and the clinical interpretation would have been differently construed. For example, on page 216 is given the case of a letter carrier of twenty, admitting an infection three and a half years previous, who became irritable and brutal to his family. The serological findings revealed a positive Wassermann reaction in the serum and fluid, the latter showing no cell increase and no excess of protein matter. Objectively there was nothing to suggest general paresis, and during twenty-one months of observation the patient was still able to attend to his duties, the clinical picture remaining the same as before. Again, on page 217 the following case is presented: A merchant who knew nothing of a syphilitic infection complained of vague pains in the back, a tired feeling, and general irritability. With the exception of unequal pupils, which, however, reacted normally, the patient showed nothing clinically. The Wassermann reaction was positive in the serum and fluid, and the latter showed neither a pleocytosis nor a globulin excess. In view of the lack of sufficient clinical signs and the absence of a pleocytosis in the spinal fluid, one should not consider these cases as syphils of the nervous apparatus, but rather disregard the positive Wassermann reaction obtained in the spinal fluid. With the original method the Wassermann result was entirely negative in the last case.

If one stops to consider the penalty an innocent patient pays as the result of a faulty laboratory report, one appreciates the necessity for greater accuracy in this work. As a rule, a patient with a positive Wassermann result is treated with antiluetic remedies. When such a patient consults
another doctor for some obscure ailment the history reveals the previous therapy and the laboratory report. Although the clinical analysis of the case shows nothing luetic at the time, the patient, in view of the previous history, is again unnecessarily subjected to specific therapy. In this instance, as a result of faulty laboratory work, various clinical entities that resemble some of the paraluetic nervous diseases would receive specific treatment and be wrongly considered either cerebrospinal syphilis or general paresis. I am almost certain that the advocate of the "Auswertungs Methode" committed such errors on more than one occasion where patients with neurasthenia, multiple sclerosis, and traumatic brain and cord lesions gave positive Wassermann reactions in the spinal fluid. Such seems to me the case (No. 3) reported on page 245. A positive Wassermann reaction was also obtained in a case of tuberculous meningitis. Some cases came to autopsy without any luetic tissue changes being found. At no time does the author of the "Auswertungs Methode" admit the possibility of a faulty report, but prefers to regard such as instances of obscure lues. It will not surprise me, if the near future proves some of the cases with positive Wassermann tests reported by Hauptmann to be either simple arterio-sclerosis, trauma, or disseminated sclerosis—at any rate, not syphilis.

I will now outline the work that permitted those criticisms and endeavor to prove my contention that at the present time there are no laboratory methods capable of detecting syphilis in every patient who may have come in contact with this disease. It must be remembered that the discoverer of the reaction himself and others who have had a large experience with it do not credit it with such accuracy. My ideas as far as the occurrence of the Wassermann reaction in neurology is concerned may be gathered from several of my previous communications on the subject, as well as from the tables and conclusions in this communication. It will be shown here that the reaction is most strongly and most frequently present in patients suffering from general paresis, and that in this disease antisyphilitic therapy has little or no influence on the abnormal serology. In cerebrospinal syphilis and in tubas, in the majority of instances, a change is noted first in the cellular increase; this, without becoming entirely normal, tends to diminish. In some exceptional cases where vigorous and persistent treatment was resorted to, it was possible to reduce the cells to a normal count; though before such a result was obtained all the other constituents of a positive serological status also became normal. It came to my notice that a few patients suffering from tubas and general paresis had no abnormality in their serological status, regardless of the fact that they had received no recent treatment. It is important to note that up to this time (April, 1913) I have not encountered a single patient with cerebrospinal lues of the meningitic or gummatous form who, unless recently and thoroughly treated, showed a negative serology. I can also frankly defend the statement made by me some time ago, that at no time should a patient be considered as suffering from general paresis where the cell count reaches the hundreds, but should be considered rather as a case of cerebrospinal syphilis, and treated as such. This is shown by two years' observation on four patients and by the analyses of three post mortem examinations. Taking into consideration certain characteristic features of the Wassermann reaction, it is often possible to determine the transition stage from cerebrospinal syphilis to general paresis by means of the cell count. The persistently positive Wassermann reaction and the cell count often permit of the anticipation of a taboparesis. It will be shown later that some forms of tubas remain not only unimproved, but are frequently harmed by antiluetic remedies. Guides for or against active specific therapy will be found in the tables and in the comments accompanying them. Up to the present time, so far as I know, no treatment has ever permanently cured a full fledged case of general paresis. I believe that where cures were reported one's attitude should be extremely skeptical, as the case may have been an unrecognized cerebrospinal syphilis.

**SEROLOGICAL FINDINGS IN TABAS.**

In four of the patients signs of a paretic dementia developed, and each was very resistant to treatment and showed no return to the normal serological picture.

In the first series of thirty-eight cases with a positive serological finding throughout, six showed the findings usually obtained in full fledged general paresis, and in two that of cerebrospinal syphilis. For a time these seemingly exceptional cases were looked upon as general paresis and cerebrospinal lues. As I believe that the laboratory findings are of only secondary importance in the making of a diagnosis, I warned against too much faith being placed on such results, regardless of the fact that a few other cases had corroborated the laboratory contention as against the clinician's attitude. It will be shown later that whereas negative findings in the fluid may obtain in tubas and in general paresis, on the other hand, positive findings are as a rule absent in fluids from the diseases scheduled under the heading of negative types. Four patients from the first group became the subjects of general paresis. The intensity of the positive Wassermann test in these patients was unchanged by the counter-acting drugs taken, and the last cell count showed less than forty cells for each c. mm. It is permissible to infer from this that one may be able to diagnosticate taboparesis from the serological findings at an early stage when only the tabetic component is clini-

1Rendered negative after treatment.
cally in evidence. One such patient began to show the signs of general paralysis after three years, during which time nine serological investigations showed that the Wassermann reaction was not in the least affected, the last cell count being twenty-seven lymphocytes to each cubic millimetre. The so-called tabes which is really a beginning general paralysis, without as yet any somatic or psychic changes, reveals its true nature first in the unchanged serological status after vigorous treatment. Among the first three groups of cases were eighty-six tabetics who showed a cell count of over sixty per cubic millimetre. These cases are designated in the table as "hyperlymphocytic tabes." These patients presented active manifestations of the disease (crises, girdle, shooting pains) which together with the high cell count were considered as significant of an exudative syphilitic condition. With but two exceptions these cases showed an improvement after appropriate treatment. A study of the table also shows that the hyperlymphocytic type of tabes does not necessarily possess a positive Wassermann reaction, or an excess of globulin in the cerebrospinal fluid. In two instances the serology resembled that of cerebrospinal lues, but the clinical interpretation and the course of the disease showed them to be tabes. It may be argued that in these cases a very active spinal lues giving the high cell count was superimposed upon the degenerative process. As no post mortem examinations were obtained in these cases, the argument remains hypothetical.

The negative types of tabes were in the majority those which had been recently treated. They presented a negative serological picture and no active signs of the disease, and were permitted to go without therapeutic interference. It was ascertained that negative tabes is best left alone, especially if no active signs exist and the condition is purely degenerative. The presentation of the serology of general paralysis makes it evident, at least in my experience, that a typical serological picture of cerebrospinal syphilis cannot be mistaken for one of typical general paralysis, or vice versa. As is sometimes the case, a clinical differentiation is very difficult, and although the clinicians in a few instances upheld their opinion of general paralysis, the autopsy proved that in these instances the laboratory contention was correct.

2 cases with 81 and 83 respectively; likely transition from cerebrospinal lues.

14 | - | + | 15 to 29 | + |
| 10 | - | + | 5 to 11 | + |

This table shows eighty-eight cases (forty-four per cent.) with the typical serological picture of general paralysis. The findings are positive throughout, and the cell count does not exceed fifty cells per cubic millimeter. The next sixty-nine cases showed a negative fluid Wassermann reaction in twenty-nine instances, which fluids showed the higher cell counts in this group, and serologically could have been considered as treated cerebrospinal lues. In fact, a vigorously treated cerebrospinal lues may give the serological reaction of tabes, as well as that of this form of general paralysis. The French school (Marie) has advanced the theory that beginning or incipient general paralysis shows a negative Wassermann reaction in the spinal fluid, and a positive one in the serum. This variety is to be seen in the third line of the table. Two cases from this group were considered by clinicians as transitional forms from cerebrospinal syphilis to general paralysis. The fourth line shows the serological status of the advanced disease as viewed by the French. These observations are corroborated to the extent of thirty-six per cent. of cases studied in the Neurological Institute, the remaining showing the early serological picture in advanced cases or the late one in recently developed general paralysis. In ten cases of unquestionable general paralysis the serological condition was entirely normal. This tends to disprove the conclusion that general paralysis always shows a positive serology, regardless of the fact that this disease is the most intensely positive Wassermann paralytic disease of the nervous system. The greatest benefits obtained from a knowledge of serological interpretations is where one is called upon to differentiate clinically between general paralysis and cerebrospinal syphilis. This need not necessarily convey the idea that the key to every obscure paralytic nervous disorder is to be found in a serological study; I say this, regardless of the fact that it often proved to be corroborative and not infrequently diagnostic. Of great importance is the typical serological picture of cerebrospinal syphilis obtained in a patient where the clinical diagnosis of general paralysis was made. The physician in such a case is warranted in proceeding very cautiously, treating his patient for the time being as a case of cerebrospinal lues, regardless of slow progress, and only after vigorous treatment has failed to improve the condition should the diagnosis of general paralysis be accepted as final. Three such patients were observed by me, all enjoying good health and attending to their affairs. These facts, and many others, tend to show the usefulness of serological investigation in nervous diseases: making the presentation of a neurological disease without it, to say the least, incomplete.

Remarks: The fluids showing no reduction had a pneumococcal agglutination of 40, 60, 100, and 160. The two nonreducing fluids showed a polyvalent agglutination of 80 and 72. In the nonredcing fluids 26 of 40 pneumococci were found. 3 cases. 17.

(To be concluded.)
SAFETY PIN REMOVED FROM LARYNX OF CHILD BY DIRECT LARYNGOSCOPY.

By Harmon Smith, M.D., New York.

Mary McD., aged two and one half years, was seen by Dr. S. T. Quinn, of Elizabeth, N. J., on February 22, 1913, at which time she was hoarse and had a dry cough, and examination of the chest revealed some bronchial rales. Examination of the throat and nose were negative. The temperature was 99.5° F. and pulse 90. The diagnosis of bronchial cough was made upon the evidence found. The administration of syrup of ipecac and a laxative relieved the condition.

Five days later he was called again, as the child had become suddenly worse, and he found marked dyspnea, a dry cough, and a temperature of 99° F. Again the examination of the nose and pharynx was negative. He called in consultation Dr. J. S. Greene, who made the diagnosis of membranous or croup, and as the obstruction to breathing had increased, an O'Dwyer intubation tube was inserted, which gave prompt relief to the obstructive symptoms but which was coughed up on the second day; 3,000 units of diphtheria antitoxin were also injected, although a culture from the pharynx proved negative. The condition of the patient improved in every respect except the hoarseness, which remained.

On March 18th, while Doctor Quinn was out of town, the consultant, Doctor Greene, was called in to see the child. The intubation tube was still in place, and he again referred the case to the administration of syrup of ipecac. On March 30th, the hoarseness still persisting, it was deemed advisable to have the advice of a laryngologist to ascertain, if possible, the cause of the condition.

On the occasion for its consultation, Doctor F. A. Norton, Wilson was called in consultation, and by means of the laryngoscopic mirror thought he determined the presence of a growth in the larynx, and concluded from the history that it must be a papilloma. He advised, however, that it be determined by the direct method, and sent her to me for this purpose.

On March 31st, thirty-seven days after the child had first been seen by Doctor Quinn, an examination was made with the Jackson laryngeal spatula, at the Manhattan Eye, Ear and Throat Hospital, and under the administration of chloroform anesthesia. Preparations had been made for the removal of the papillomata, if present, and for the introduction of a tracheal tube, provided they were not of a malignant type. Nothing was found filled the larynx, and the breathing was of an obstructive character, which necessitated rapid work to obviate performing a preliminary tracheotomy. After the mucous had been removed from the larynx, a bright object was seen protruding from between the vocal cords. With a pair of ordinary straight laryngeal forceps it was grasped and extracted, without difficulty and without hemorrhage. The patient's breathing immediately became less labored, and the cyanosis improved. On the following day the patient was sufficiently well to be taken to her home in Elizabeth, N. J., where she made an uneventful recovery. For several weeks the voice remained somewhat hoarse, but in a subsequent report from Doctor Quinn he stated that the voice had returned to normal and there was no sequence to her unique experience.

The important facts in this case are, the liability of physicians, unsuspecting the presence of a foreign body, to diagnosticate the case in accordance with the symptoms presented, without utilizing the X-ray as an infallible method of determining its presence; secondly, that an intubation tube could occupy the larynx at the same time with the safety of the patient in giving evidence to the operator of its presence, and that the tube could be coughed up and the pin remain in situ; thirdly, that the absence of microscopical evidence of the Klebs Loefler bacillus in the examination of a specimen from the pharynx should direct the attention of the physician in charge to something else as a causative factor, although in many instances diphtheria can exist where the superficial culture will not reveal the presence of the infection; fourthly, that the examination of a child's larynx by the laryngoscopic mirror, although performed by an expert, is inadequate, owing to the struggles of the child, the smallness of the larynx, and the presence of mucus which cannot be removed and which obscures the character of the body or growth.

THE ETIOLOGY AND TREATMENT OF HYPERTRICHOSIS.

By Paul E. Bechet, M. D., New York.

Assistant Physician, New York Skin and Cancer Hospital; Attending Dermatologist, Roosevelt Hospital Dispensary; Assistant Dermatologist, Presbyterian Hospital, Out-Patient Department.

The importance of this abnormality is, in my opinion, too frequently underestimated by medical men. The tendency to bemoan the operation of electrolysis, to consider it only as a beautifying measure, and not worthy of serious attention, is to be deplored. The result of this policy causes a number of women suffering from this unsightly defect to resort to "beauty specialists," accommodating druggists, or skillfully advertised, and often harmful, depilatories. Hydrogen peroxide and ammonia, pumice stone, epilation, depilatories, various skin creams, and unskilful electrolysis, are tried one after the other; coarse hairs made coarser, downy hairs transformed into coarse ones, unsightly scarring, follicular infection, and eczematoid dermatitis are some of the sequelae which frequently follow such attempts.

The frequent association of at times serious mental depression and melancholia is a fact which has been insufficiently noted in the literature on the subject. A considerable proportion of the patients I have seen were extremely sensitive about their condition, this sensitiveness amounting at times to the highest degree of mental anguish. One of my patients gave up a very lucrative position, shunned all her acquaintances, refused to go out unless heavily veiled, and slowly drifted into true melancholia, because of her excessive polytrichia. Her mental condition became entirely normal after the removal of the superfluous hair. The amount of mental suffering which these patients go through is surprisingly great, judging from their gratitude after recovery.

There are only two plausible theories as to the cause of this anomaly, namely, heredity and functional or organic disorders of the uterovarian system. That there are a number of instances of this condition arising in generations of one family cannot be denied. Even universal congenital hirsuties has been observed in some families. a good example being the much quoted "Russian dogfaced man" (Andrian Jetchjeff) and his son; but, in spite of these instances, I do not believe heredity plays an important rôle in the causation of hirsuties. I have, through the courtesy of Dr. L. Duncan Buikley, been enabled to combine some of his clinical histories with mine, and have a total of one
hundred and forty-six cases, in which etiological factors have been thoroughly gone into, and there are surprisingly few in which heredity seemed to be a possible cause. Time and again patients deny any family history of hypertrichosis. Of course, it cannot be gainsaid that, in some families, especially of the brunet type, excessive hair growth is common, but it does not invariably develop into a noticeable hirsuties.

The connection between hypertrichosis and the internal organs of generation is, in my opinion, a much closer one—for instance, the growth of hair on the male chin and lip, which occurs only at, and slightly beyond puberty, is certainly the result of the action of some new formed unknown secretion, probably of testicular origin. The influence of the uteroovarian system and normal sexual life is well brought out in the analysis of the cases previously alluded to. Of 146 cases analyzed, 106 patients were unmarried. In none of the cases did hypertrichosis occur before the establishment of puberty. Of the 106 single women, only four were less than eighteen years of age—two were sixteen, one fifteen, and one fourteen; in all four puberty was well established.

In noting the number of abnormal menstruations I have endeavoured to be most conservative, and have been careful to exclude all but the most serious abnormalities, so that, of the 146 cases, eighty patients were found to have severe menstrual disturbances, but fully twenty-five per cent. of the sixty-five remaining patients had minor anomalies of menstruation. A considerable number of cases of spontaneous disappearance of superfluous hair after pregnancy, or the reestablishment of the normal flow following a prolonged amenorrhea, have been reported. Jackson observed a woman who, after having borne several children, suffered from a persistent amenorrhea, during which time an extensive hirsuties developed. Several years later she again became pregnant, and, after the birth of the child, the growth spontaneously disappeared. Hyde reported a married woman, thirty-three years of age, mother of three children, who had not menstruated for over a year. She had a general and facial hirsuties. After some years she began to menstruate, and the hypertrichosis of the general surface spontaneously disappeared—the facial hirsuties having been previously removed by electrolysis. In all reported cases of the early development of pubic hair, menstruation apparently invariably occurred. Lesser reports a girl of six with extensive hair growth, who had been menstruating since the age of three. In view of all these facts, it seems to me perfectly plausible to believe that hypertrichosis is the result of a functional or organic derangement of the ovaries, whereby some unknown hormone, with a specific influence on pilosity, is so altered in character that pilosis results.

For the permanent and safe removal of superfluous hair nothing has as yet been able to supersede the operation of electrolysis. The x ray at first promised brilliant results, and most enthusiastic reports were made, but the subsequent dermatitis, atrophic changes, or telangiectasis which so frequently followed its application, caused a reversal of the favorable opinion first held, and many now refuse to use it. Considering that the removal of superfluous hair is entirely a matter of cosmetics, one should hesitate to use such a powerful agent, so capable of ultimate harm. It should be used only in those cases not otherwise amenable to treatment, and the exposures made by an expert only. As Norman Walker aptly says, "No beginner should use the x ray for this condition save in his own family."

Electrolysis, on the other hand, is entirely harmless, and, in the hands of the skilled, results are permanent and perfectly satisfactory. Poor results are entirely caused by inexperience on the part of the operator. There is no dermatological procedure which requires more practice to master. As every operator has, more or less, a different method of doing the operation, I shall describe my own.

My apparatus consists of a galvanic battery, with the street current as motive power, a milliamperemeter, a rheostat, connecting cords, foot switch, magnifying glass, head light (for use on dark days), needle, needle holder, sponge electrode, epilating forceps, and fifty-five per cent. alcohol. The strength of current used is from one half to one and a half milliamperes, one milliamper being the average. As the meter is the only way of measuring the current, it is an absolute necessity. What takes place at the site of the operation is no indication of the strength of the current, and much scar ring would be prevented by an accurate knowledge of the amount of electricity used.

The needle with the holder is attached to the negative pole, for if attached to the positive pole, a steel needle will become oxidized, iron rust will be deposited in the tissues, and a bluish black stain result. The needle I use is iridiumplatinum—I have found it much less painful than a steel one, and it has the added advantage of pliability. The needle holder should be light, and capable of easy manipulation. The foot switch brings the current entirely under the control of the operator and prevents the tiresome and oft repeated requests to the patient to make or break the current. The head light is a great convenience on dark days, and at night. The site of operation is swabbed with ninety-five per cent. alcohol, which, besides being antiseptic, acts as an anesthetizer, and dissolves fatty accumulations at the follicular openings, thereby facilitating the entrance of the needle. The needle is rinsed in alcohol, and frequently dipped in it during the course of the operation. The patient is seated in a chair with a movable back and head rest facing the light, and is given a damp sponge electrode, which should be held in the palm of the hand. The needle is introduced into the hair follicle, alongside of the hair, down to the papilla, the depth of which varies from about one sixteenth to one quarter of an inch.

A sense of resistance is usually an indication that the papilla has been reached. The current is then turned on, by placing the foot on the foot switch, and allowed to flow for from ten to sixty seconds, according to the size of the hair. Frothing and bubbling at the point of entrance is due to the formation of hydrogen, the result of chemical reaction, and is not a positive indication of the destruc-
HARROWER: SECRETIN IN GASTROINTESTINAL DISORDERS.

SECRETIN AS A REMEDY IN GASTROINTESTINAL DISORDERS.

By Henry R. Harrower, M.D.,
London, England,
Late Professor of Clinical Diagnosis, Loyola University, Chicago, Ill.

For many years preparations of animal origin have taken an important place in the orthodox treatment of certain forms of indigestion. The use of pepsin and pancreatin has been established on a firm basis, although at times dissentient voices are heard to the effect that the continued use of such preparations tends to induce laziness on the part of the organs in question. Our conception of the treatment of the indigestions has in the past few years been very materially modified. The discovery of certain other substances also of animal origin has begun a revolution, not only in our conception of the physiology of the digestive glands, but in the treatment of their functional disorders.

The most notable of these remarkable substances is the hormone "secretin," first isolated by Starling and Bayliss in the research laboratories of University College, London, in 1902 (1). It would appear that in this substance we have a most valuable and reasonable remedy for many forms of indigestion; a recapitulation, therefore, of some of the fundamental facts regarding its application is appropriate. Hitherto experimental investigators have used this substance, and these, usually, not in clinical work. It is still the exception to find physicians using secretin as a therapeutic agent.

Secretin is a definite chemical product of the mucous membrane of the pyloric end of the stomach and the duodenum. The story of its discovery may be briefly recalled: On the investigation of the properties of enterokinase, that remarkable trypsin activator first discovered in Pavloff's laboratories at St. Petersburg, Bayliss and Starling noted that the injection of acid or acid chyme into a loop of small intestine was followed by a secretion of pancreatic juice, even when all nerve channels had been destroyed. These investigators were convinced that the message from the intestine to the pancreas was not carried by the nervous system, but by the blood; they presumed, therefore, that the activating substance was produced in the duodenal walls under the influence of the acid, and that it was then absorbed into the blood and served to excite pancreatic function. A portion of the intestinal mucous membrane was accordingly scraped, pounded up with dilute hydrochloric acid, and filtered. Injection of a portion of the neutralized filtrate into the blood of an animal resulted in a copious flow of pancreatic juice, and the chemical messenger or hormone responsible for this action was named "secretin." Later it was called "pancreatic secretin," to distinguish it from other similar substances which excited other glands (2).

Since this epoch making announcement was made other investigators, notably Edkins (3), have shown that the gastric walls near the pylorus produce a similar secretin which has been called "gastrin" or "gastric secretin." Its action is through the blood and upon the peptic and oxyntic glands of the stomach.
In a recent editorial reference to The Gastric Secretin (4), the results of this work are outlined as follows:

Edkins has carried out experiments to see whether such a chemical mechanism, in distinction from the nervous control which is usually called on to elucidate the phenomena of secretion, may not also serve to explain the secretion of the gastric juice when food is introduced into the stomach. He finds that substances such as peptones, broths, dextrin, etc., which are known to induce gastric secretion when ingested, are without influence on the secretary act if they are injected directly into the blood stream. But when such known excitants of secretion are allowed to stay in contact with the pyloric mucous membrane, and a deoction of this is then injected into the circulation, a secretion of both acid and peptic enzyme into the stomach ensues. Infusions of the cardiac portion of the stomach or of other organs do not act in this secretion producing manner. Edkins concludes that this typical secretion of gastric juice is determined by a chemical mechanism; the first products of digestion act on the pyloric mucous membrane, in which they produce a substance which, entering the blood stream, is carried to the gland cells of the stomach, where it acts as a specific excitant of their secretory activity. This is the gastric hormone—gastric secretion.

The St. Petersburg School has long opposed the "secretin theory." Bylina, in 1911 (5), intimated that secretin was not quite what Bayliss and Starling had made out, stating that the pancreas possesses a constant secreting function for which nervous influences are principally responsible. Later (6), he admits that the pancreatic secretion to a certain extent is dependent upon a humoral mechanism; but he still asserts that nervous influences are concerned in the excitation of pancreatic secretion and, indeed, determine the chemical character of the juice. L. P. Topielski insisted similarly that secretin played a minor part in the activation of pancreatic juice, and that the results purported to be due to its influence were obtainable in other ways.

Experiments seem to discount these statements, and the most conclusive proof of the fallacy of Bylina's idea is to be found in a 100 page thesis (7) which gives the details and deductions of Hurin's study of the mechanism of the external secretion of the pancreas. The subject is very thoroughly discussed, the importance of secretin being emphasized in a convincing manner and certain of the experiments being most decisive. Among other things it is interesting to note that Hustin has demonstrated that the pancreatic secretion cannot be stimulated by secretin alone. He has proved that a certain element in the blood must be associated with the secretin. His method consisted in taking the pancreas from an animal, placing it in a bath of paraffin, and then irrigating it with liquids, which were introduced by means of a cannula through the pancreaticoduodenal artery, and were conveyed away by another cannula in the portal vein. A third cannula was introduced into the duct of Wirsung, to lead off the pancreatic juice. As a result of numerous experiments the author established the important fact that a gland irrigated independently with physiological serum (Locke), blood, or secretin solution gives no secretion; but irrigation with a mixture of blood and secretin gives an abundant secretion of clear liquid containing trypsin, lipase, and amylase. The author further states that secretin is used up in the gland in the impregnation of the pancreatic cell, in a manner that renders it sensible to the action of certain substances in the blood. The presence of calcium electrolytes is a third essential.

For convenience, Hustin compares this action with the side chain theory of Ehrlich, viz., that living protoplasm carries certain chemoreceptors, or contains chemoreceptive substances, and it is by combination with these that drugs, etc., induce their specific effects.

Recent reports from St. Petersburg seem to indicate that at last there is a tendency to admit that the "secretin theory," so long discounted by certain Russian and Italian physiologists, is no longer so untenable. Sawitsch and Zeleny (8), reporting a series of experiments which were carried out in the physiological laboratory of the Military Medical Academy in St. Petersburg, have established the essential accuracy of Edkins' contentions that normal gastric secretion is due to the cooperation of at least two factors; the one a nervous secretion induced by the stimulation of the mucosa of the mouth or by the awakening of the appetite through psychic channels, and the other a chemical factor dependent on the elaboration of a hormone which acts as a chemical messenger to all parts of the stomach through humoral paths, and whose effects linger long after the psychic stimulus has disappeared.

In his book on The Action of Medicines (6), Sir Lauder Brunton illustrates his statements by means of a diagram (Fig. 2). This diagram (for the use of which I have cordially to thank this dis
HARROWER: SECRETIN IN GASTROINTESTINAL DISORDERS.

In my opinion the analogy is not as thorough as the foregoing quotation would indicate, for the use of secretin and other hormones is much more reasonable, and its stimulating effect far more nearly physiological, than that of other means to the same ends.

Secretin is not particularly difficult to obtain. As already mentioned, Starling secured it by pounding up duodenal scrapings with hydrochloric acid. Various methods of extracting secretin are outlined in articles by Bayliss and Starling (13), Stepp (14), and Launoy (15). Aqueous solutions of secretin are easily made; but they must be used while fresh, as, if left unstoppered, they lose their activity in about twenty-four hours. If, however, they are preserved in sterile ampoules and kept in the dark they remain active for a long time. Fortunately, dried extracts of duodenal mucous membrane keep well, and from them potent solutions can be easily prepared as desired. Several trade preparations are now made in America, France, and England. It is provided that in this manner one can stimulate the production of hydrochloric acid in the stomach, the rest is simple. The passage of the acid gastric contents into the intestine will be a natural stimulus to the production of secretin, so that the administration of such a remedy serves a double purpose. Not only will it stimulate the pancreas directly, but also indirectly by the production of an additional supply of this important activator.

In practically all animal experiments with secretin, this substance has been administered by the intravenous method, and it has been stated that secretin when taken into the stomach is not active. Some experiments have been made the results of which indicate that in animals secretin is not absorbed when introduced even in large doses into the digestive canal. Undoubtedly the comparisons between the intravenous injection of secretin solutions and the oral administration of solid or liquid secretin preparations would give evidence in favor of the direct method—intravenous medication, for obvious reasons, is more rapid, active, and pronounced than any other method of giving drugs—but, such statements to the contrary notwithstanding, one can overlook the noticeable influence on digestion and nutrition following the administration of secretin by mouth. This will be still more apparent when all the evidence gathered in this paper is considered. It must also be remembered that, in the preparation of secretin, boiling with dilute hydrochloric acid is a part of the process, and any conditions which might be found in the stomach would seem theoretically to be negligible; in fact, in practice the oral administration of secretin accomplishes definite results which are sometimes nothing short of marvelous.

At present there is a paucity of literature on the clinical use of secretin. There are numerous references to its physiology, and in the French literature there are many interesting papers. In one of these Halchin (16) notes that secretin has also a distinct influence upon the liver and the motor functions of the bowel. In his experiments, in which he was associated with Enríquez (17), he noted that secretin also increases in a great measure the secretion of bile. This fact has also been confirmed by
Portier, Falloisc, and others. He also calls attention to other physiological data which he has secured, and refers to a statement by Delezenne and Frouin (18) to the effect that "the action of secretin is not limited to the liver and pancreas, but extends to the intestine and influences the production of succus entericus." Enriquez, in a communication to the Paris Academy of Medicine, writes (19):

"Based on the greater importance to normal digestion of the production of secretin in the duodenum, why should not, clinically, a large number of dyspepsias be secondary to a disturbance in the highly specialized function of the duodenal mucosa? When it is remembered," he continues, "that secretin also possesses an incontestable influence upon intestinal motility, one of the first and most constant signs of secretin insufficiency must without doubt be clinically represented by constipation. Thus, guided by our experimental research, we have found a means of stimulating this function in certain constipated dyspeptics." Enriquez prepared keratin coated capsules of gluten, containing an active and harmless acid (tartaric), which was proved experimentally to be stable in the stomach and easily destroyed in the duodenum.

The results of this form of medication were most interesting. All the patients showed a more or less noticeable constipation, and in seven of the cases it was the dominating symptom, inconveniencing the patients as much by its persistence as by its obstinacy. In these seven cases acid medication of the duodenum brought about, with varying ease, according to the dose, a stimulation of the secretory and motor functions of the intestine and a regulation of the stools. Two cases were of special interest. One was that of a person suffering from localized sclerosis ("sclérose en plaques") for many years, with intractable constipated periods lasting from six to eight days, and which resisted all kinds of purgatives, enemas only having any action. Under this treatment the stools were immediately regulated, giving way again to constipation as soon as the treatment ceased, this occurring several times. In five of the observations mucomembranous colitis was complicated alternately with constipation and painful abdominal crises, terminating by the passage of glairy mucous and membranous casts. In four of the cases the colitic symptoms were much relieved at the same time as the constipation.

Of course, the principal value of the method of treatment outlined above depends upon the production of secretin. There may be cases in which the duodenal cells will not be stimulated, and here it would seem that secretin itself could be used to good advantage. I have personally noticed, and my experience has been confirmed by several correspondents, that the administration of preparations of secretin is followed quite constantly by the relief of fermentation and flatulence in the upper bowel, and the reason for this is not far to seek. The principal cause of gastric and intestinal fermentations is a deficiency in the amount and activity of the digestive juices. It has long been known that the administration of hydrochloric acid not only favors the digestive action in the stomach, but also tends to increase the amount of pancreatic ferment in the duodenum, and only since the discovery of secretin has it been clear how this is brought about.

Very little clinical work seems to have been done with secretin in the United States. The only article referring to a secretin preparation that I have been able to find is from the pen of Boardman Reed (21). In this article he compares his standard peptic hydrochloric mixtures, referred to in his excellent book, with an elixir containing gastric and pancreatic secretions, and finds that these organic principles are considerably more active, rapidly bringing the work of the stomach to the normal, and, usually, at the same time improving the intestinal indigestion and assimilation. Reed states that secretogen is apparently the most powerful excitant of gastrointestinal secretion so far tried by him, and refers to a number of cases, one of which is mentioned in an addendum to his paper, which follows: "Since the foregoing was written I have examined chemically the stomach contents of one of the patients referred to, in which none of the secretogen has been taken for a month, and the proportions of both the free and combined hydrochloric acid were found still a little above normal, though, before the remedy was taken, there had been no free hydrochloric acid at all, and the proportions of both the combined hydrochloric acid, and of the total acidity, had been decidedly below normal."

Moore (22) of the Biochemical Department of Liverpool University, has called attention to deficient secretin production in cancer and gastric cancer. It is well known that achlorhydria is an almost constant symptom of this disease, and the lack of hydrochloric acid—the physiological stimulus to normal secretin production in the duodenal walls—results in a marked decrease in the amount and effectiveness of pancreatic ferments. This nearly affords to account for the nutritional disorders which are pathognomonic of carcinoma. With the foregoing in mind, it can be readily appreciated that secretin may be used in cancer and cachexias generally, not to influence the disease per se, but rather as a means of increasing the digestive activities and nutrition. The same ideas naturally hold good in other conditions where toxemia, superfec tion, or asthenia, has lessened the digestive capacity. In no disease is this influence more desirable than in tuberculosis, and attention is already being turned to the possibilities of this new adjunct remedy for tuberculosis (23).

Secretin has been recommended as a means of treating diabetes, and much was expected from its use because several very good results occasionally followed its early administration in this disease. The basis of this study was the clear physiological evidence of a connection between pancreatic activity and diabetes, as well as between secretin and pancreatic activity, and that where functional disorder of the pancreas was present advantage might be expected to follow the stimulus caused by secretin. In their first communication on this subject, Moore, Edie, and Abram (24), described three cases of diabetes in which improvement followed

---

1. The writer has drawn special attention to the possibilities of secretin as a factor in the control of the summer indigestions of infants (20).

The oral administration of an acid extract of duodenal mucosa. As a result of this treatment, the sugar diminished gradually, and finally disappeared. Later these same authors (25), whose work in the meantime had been augmented by the discovery by Bainbridge and Beddard (26), that in many diabetics prosecretin is absent from the duodenum,1 admit that the majority of cases treated in this manner showed no appreciable change in the sugar output. They call attention, however, to the fact that "in some of these negative cases there has been noticed an improvement in the digestion, and in certain cases the patient's weight has increased."

In one case in particular this incidental influence on digestion was very decided. "Almost at once the dyspepsia from which he was suffering was relieved, and his general nutrition improved to such an extent that he regained over eighteen pounds in weight, and this improvement was accompanied by a complete recovery of his mental and physical energies" (25). It seems, however, that these failures are due, not to the lack of activity in secretin, or to its administration, but rather to the fact that the external secretion of the pancreas plays a very minor part in the carbohydrate metabolism. The internal secretion, on the other hand, has a specific influence on sugar combustion, due in all probability to the so called "Langerhansian hormone," which is now known to antagonize the chromaffin hormone produced by the adrenal system, and that the influence of secretin on the production of the internal pancreatic secretion is almost negligible, or at least, decidedly less than upon the digestive or external secretion.

CONCLUSION.

Without further dilation upon this most interesting subject, the principal facts regarding the therapeatic possibilities of secretin may be briefly stated:

1. Secretin is a specific excitant of all of the important digestive juices—pancreatic, gastric, hepatic, and intestinal.

2. It may be secured just as are other animal extracts, and it has the advantage of being a definite, stable preparation.

3. It may be given by mouth with good results in the large class of gastrohepatointestinal disorders described under the general head of "digestive insufficiencies."

4. Such medication is absolutely physiologic, as in certain cases it seems that secretin is a necessary substance which the body is not supplying in its normal amount (just as thyroidin supplies to the athyroidic a most necessary hormone, the lack of which happens to be more definitely manifest).

5. Secretin is not a digestant, having no influence whatever comparable with that of peptic or pancreatic, but its fundamental value is superior to these fermentations, as well as to other forms of stimulation, such as chrymine, ginger, etc.

6. The administration of secretin is quite harmless, causes no habit, and does not interfere with other orthodox treatment, and its administration may with advantage be associated with digestants, tonics, etc.

It seems clear, therefore, that the use of hormones as therapeutic agents—and in particular the use of secretin in various forms of indigestion—is destined to become much more general, and as the foregoing statements become further confirmed by clinical experience, the present day treatment of gastro-intestinal disorders will be augmented, if not revolutionized.

IMPORANCE OF EARLY OPERATION FOR THE RADICAL CURE OF HERNIA.

By H. W. AUSTIN, M. D.,

Port of New York (Stapleton), Senior Surgeon, United States Public Health Service.

In my experience in the hospital treatment of adults suffering from hernia, I am impressed with the facts that a large proportion of the patients were men who had large scrotal hernia acquired some years previous, and that the number who applied for
LEMOX: PHOSPHORUS IN PULMONARY DISEASES.

NEW YORK MEDICAL JOURNAL.

relief for recently acquired hernia was proportionately small.

I have operated for the radical cure of hernia 265 times (including all varieties—inguinal, femoral, umbilical, ventral, strangulated inguinal and umbilical, and large irreducible scrotal hernia containing bowel, appendix, and omentum) successfully, with no serious result due to the operation in any case. The one unfortunate result was a death from ether before the operation, the only death that has occurred from anesthesia in my practice. While I have fortunately met with no serious results in operating for the radical cure of very large irreducible scrotal hernias containing bowel, I fully appreciate the difficulty and gravity of the operation in elderly men, and it is the purpose of this paper to emphasize the necessity for early operation for hernia to obviate the inconvenience, disability, and danger to patients, especially laboring men, in temporizing or postponing operation until their hernias are so large that they become practically disabled. The seriousness of the operation and the permanency of the cure depend in a large measure upon the age of the hernia. The inconvenience of wearing a truss and the danger of strangulation are avoided by early operation. If complete histories of all cases of hernia could be obtained at one time, it would be found that there is a close relation between the duration of the hernia and the size, degree of disability, risk from strangulation, risk from operation, and probability of permanency of cure by operation.

In recently acquired inguinal hernia the operation for radical cure is a simple operation, entailing scarcely any risk to the patient, quickly performed under local anesthesia. It affords almost certain guarantee of permanent cure. In very large inguinal hernia of long standing, irreducible, the sac containing bowel, omentum, etc., the operation for cure is always more or less serious and the chances for a permanent cure less certain. Cases of this kind should be undertaken only by an experienced operator. Occasionally cases of old and very large hernia are seen that are absolutely inoperable; cases in which an operation would promise no permanent relief and the risk taken would be unwaranted. I have seen several cases of this character in old men.

Usually an old hernia that has not been carefully retained by a truss is a large hernia, and the sac frequently contains bowel and omentum which are firmly adherent to the cord and sac throughout. I operated upon two patients having this kind during the past year, men who were sixty years old. They were, before the operation, entirely disabled for any kind of work; their hernias were very large. A considerable portion of the omentum was excised before the bowel could be returned. There was a good result in both cases, but the operations were both difficult, requiring careful dissection and prolonged general anesthesia, and were not without danger to the patient. I reported a number of successful operations for the radical cure of hernia in 1886 and in 1890 upon patients who were completely disabled prior to the operation.

The inguinal canal in these cases is entirely obliterated by pressure of the sac upon the transversalis fascia causing its atrophy: extending the internal ring as low as the external and making a direct opening at the neck of the sac from one and a half to two inches in diameter. To close this large opening in the fascia is not always easy, and we must depend upon the muscular tissue for the support, usually the internal oblique and transversalis, which in some cases are also atrophied. The edge of the rectus may be brought over, but the permanency of the cure in very large old hernias is not certain, while in recent hernias the operation almost always affords a permanent cure. In recent inguinal, femoral, umbilical, or ventral hernia the operation for cure can be safely performed under local anesthesia in persons of all ages. But a few weeks ago I operated for complete oblique hernia upon a man seventy years old under local anesthesia. The Bassini operation was performed, and it required but twenty minutes. The patient suffered no pain nor inconvenience except that of having to remain in bed one week, when the wound was perfectly healed and a permanent cure effected. It requires but from fifteen to twenty minutes usually to do the Bassini operation in a recent hernia (it can be done in some cases in ten), while in very large, old irreducible hernia it may require an hour and a half. Where hernia occurs in young children early operation is no doubt advisable, but I have had little experience in operating upon children.

There are physicians to-day who are prescribing trusses for their patients suffering from all varieties of hernia, and others who, while they recommend an operation, do not fully explain the advantages of an early operation. There are many people, however, who when they first find they have a hernia go directly to some druggist and buy a truss, and continue to wear one until they become partially disabled. We find many of the latter cases in the Service hospitals.

Hernia is probably the most frequent natural anatomical defect found in the human body. It occurs in about one out of every thirteen male persons during life, and thousands of laboring men are at the present time more or less disabled on account of it. The degree of disability depends to a great extent upon the occupation of the person, it being greatest in those engaged in physical labor, and it varies from partial to complete. I have seen a number of persons with an inguinal hernia sac extending nearly to the knees, which they suspended in a bag attached to a waist belt. These are merely mentioned as examples of complete disability. All such cases can be prevented, as well as others of less degree of disability, by early operation, and I believe that it is an obligation which every physician owes to his patients to fully explain the importance of early operation in hernia, and advise them not to seek relief from trusses, from the use of which they become disabled, nor to wait until an operation becomes a serious matter.

UNITED STATES MARINE HOSPITAL.

THE USE OF PHOSPHORUS IN DISEASES OF THE LUNGS.

By FERGUSON LEMOY, M. B., B. S., Melbourne, Australia.

So far as I have been able to ascertain by reference to literature and records, no mention, for the last thirty years at least, can be found of phos-
phorus, in the pure state, having been administered as a therapeutic measure in the treatment of diseases of the lungs. During the past eleven years this drug has been exhibited by me in all classes of cases in lung disease, acute, subacute, and chronic, and the result leads me to the belief that in pure phosphorus a most potent agent exists for the restoration of patients suffering from these diseases.

On entering the profession I became a partner in a large suburban practice and during the first six months, owing to my partner's absence in Europe, I personally conducted the whole of the practice. Before his departure we had an incidental talk over treatment of different kinds and he gave me, among others, a hint, that in all cases of acute lobar pneumonia; the exhibition of pure phosphorus in small doses, that is from 1/1000 to 1/200 of a grain, at fairly close intervals, would bring about an almost marvelous shortening of the crisis. He was specially referring, while on this subject, to a particular patient, very far advanced in pulmonary tuberculosis, who had a special symptom of recurrent hemorrhages at three monthly intervals. These hemorrhages gave rise to an acute form of pneumonia and he had found in his experiences that phosphorus in 1/500 grain doses had a wonderful effect in bringing the patient back to his normal condition.

PULMONARY TUBERCULOSIS.

It was not many weeks before the patient referred to had one of his recurrent hemorrhages. After the initial dose of morphone had been injected, phosphorus in 1/500 grain doses was administered every alternate hour, and it was rather remarkable to see how rapidly this patient recovered from the posthemorrhagic pneumonia.

When the patient was his normal self again, a thorough examination of his chest was made. It showed the whole of his right lung riddled with large vomicje, loose bubbling râles all over, back and front, and all the other accessory signs of advanced pulmonary phthisis. The apex of the left lung very closely resembled that of the right lung; then after a fairly wide belt of absolute consolidation, the lower lobe, though free of consolidation, was markedly infected with early tuberculous disease; fine crepitations were heard all over the lower part, and prolonged expiration and increased vocal resonance were marked. A picture, on the whole, of very widespread tuberculous degeneration. So advanced was this condition that it is a wonder he continued to exist at all, much less to carry on his work, that of a proof reader to a large publishing firm in Melbourne, in the intervals between the attacks.

For some years he had been treated in the orthodox fashion for phthisis, that is by nourishment, principally in the form of large quantities of milk, creosote, etc. He was little more than skin and bone, and to the casual observer he was past all possible hope of improvement. He had always resolutely refused to sleep in the open air.

Seeing the wonderful effect that phosphorus had had on his condition the question arose, would the prolonged exhibition of this drug give rise to any further improvement? He was asked, if, as an experiment, he was prepared to carry on a course of treatment for, say, three months. After some demur he eventually consented.

Nothing was changed as regards his ordinary way of living but he was advised for the first month, at least, to give himself up to the treatment and rest instead of going back to work. This he did, taking notes of his case and keeping a chart.

Hitherto he had suffered from copious night sweats and occasionally profuse expectoration. The first two marked symptoms noticeable at the end of the first week or ten days were continual excessive expectoration and a diminution of the night sweats. The former continued to increase rather than diminish during the first six weeks, but at the end of that period a night sweat was an unusual phenomenon. The cough up to this stage had been very loose and the sputum had been brought up without any effort.

After this period the cough commenced to be harder and the sputum perceptibly lessened every day while the temperature in the evening, which had always gone up to 100° F. or more, during the first few weeks, greatly declined till it was rarely above 99° F. From the tenth week onward the cough was practically the only troublesome symptom; the night sweats had completely disappeared and the sputum was practically nonexistent.

On examination of his chest, at the end of three months, the right lung which had practically been filled with a copious secretion in the early stages, appeared comparatively dry; moist sounds were a rarity and the air passed freely in and out of the numerous vomicje. The left lung also showed signs of marked improvement and though the consolidation band seemed as dense as hitherto, the fine crepitations in the lower lobe had almost disappeared; the breathing was harsh and puerile; prolonged expiration continued; vocal resonance was still very marked.

His bodily condition at the end of the third month was greatly improved; though he had not been weighed before starting the course of treatment, he appeared to have put on at least a stone (14 pounds) in weight, looked very well, and very different from the dying appearance of three months before.

He returned to his work, taking one dose of 1/500 grain of phosphorus daily for the next three months and, with the exception of an occasional friendly visit, was not attended again for hemorrhage during the next three years when professional relation with him ceased. It was not till some years afterward that he was seen again and hardly recognized. He made himself known in the street. He was then looking very well, and stated that he had not had to see a doctor since his treatment. It was not till twelve months ago, in January, 1912, that we met again casually and he said that, with the exception of some hemorrhage in the bladder, he had been perfectly well. He is now over sixty and, though probably he has not more than half a sound lung, is comparatively healthy and still able to carry on his work.

The result of this experimental treatment inclined to the belief that phosphorus had a very valu-
able effect in the treatment of consumption, and during the past eleven years case after case of pulmonary tuberculosis has been treated by its means, and in only a very few cases out of over one hundred have its results been disappointing.

While the use of phosphorus as the main active principle in the treatment of all cases of pulmonary tuberculosis has been retained, the addition at various times of other drugs has been made with a view to enhancing the general value of the treatment. Where patients have been too feeble and would have rejected stronger measures, treatment has been commenced with extremely small doses of phosphorus, then as they improved in condition, such drugs as calcium hypophosphite, arsenous iodide, and ferrous iodide were added, these being introduced to provide calcium in an easily absorbable form, arsenic and iron with the object of improving the blood, and iodides to assist in the absorption of the toxic products.

While in most cases the patients have been able to take the full strength of the prescription during their treatment, several of them have exhibited intolerance for iodine even in small doses, whereupon this product was deleted from the prescription. Where the patient is considered strong enough to stand the full treatment the following prescription is generally given:

R  Calcii hypophosphitis, .................. 5s—ij; Tincture phosphorii (1:100), Liquori arseni iodidi (1:100), 6s—ij; Syrupi ferri iodidi, 5s—ij; Aqua, q. s. ad 5v.)

M. et Sig. : One dessertspoonful four times a day after food and at bedtime, in water.

_Diet Chart:_
7 a.m. Glass of hot milk and a biscuit.
8 a.m. Warm sponge bath. Rest till 8:30.
8:30 a.m. Breakfast: Porridge, eggs, bacon, fish, large cup of milk coffee, bread and butter, honey, etc.
9 a.m. Medicine.
9:15 a.m. One dessertspoonful of malt and cod-liver oil.
10:30 a.m. Rise from bed.
11 a.m. Basin of milkbroth and dry toast.
11 to 12 a.m. Short exercise in the open air.
12 to 12:30 p.m. Dinner. Any white meats, vegetables, milk puddings, stewed fruits, etc. Glass of milk.
1 p.m. Medicine.
1:15 p.m. Malt and cod-liver oil.
1:15 to 3 p.m. Rest or quiet exercise in open air.
3 p.m. Large cup of milk tea and cakes.
3:30 to 6 p.m. Rest or quiet exercise in open air.
6 p.m. Tea, fish, eggs, etc., large cup of milk.
cocoa, bread and butter, jam, honey, etc.
6:30 p.m. Medicine.
6:45 p.m. Malt and cod-liver oil.
8:15 p.m. Medicine.
9 p.m. Retire to rest in open air.
9:15 p.m. Glass of hot milk.

This prescription, as already remarked, goes to form the basis of all general treatment of tuberculosis, but it is altered according to the capacity of the patient, drop doses of phosphorus being given well diluted with milk where the stomach rejects stronger measures.

While this is the basis of all general treatment the ordinary approved methods of rest, graduated exercise, and sleeping in the open air treatment and feeding are not neglected. Sleeping in the open air has often been impracticable on account of the obstinacy or poverty of the patients, as in Cases 1 and 11, and this specially refers to Case 11, in which the patient was confined during the whole of her treatment to a small ill ventilated room.

During the past four years high frequency current has been given twice a week during treatment to some of the patients, each patient completing the actual course in three months. However, they generally take a month's course of medicine at the sixth, ninth, and twelfth months. This treatment has met with almost unbroken success, notwithstanding the fact that all classes and conditions of tuberculous disease in every stage from earliest to latest have been treated. The conclusion has been arrived at, that where patients have any power of resistance at all they make a good recovery to health, and though the signs of trouble, particularly in the later stages, remain, all active symptoms disappear. No patient is considered cured till the sputum is absent, or if any sputum should still be present all trace of bacilli is lost.

The few failures that have been experienced were advanced cases where the whole lung was involved, the larynx greatly affected, and digestion impaired, and where the patient’s power of resistance was destroyed by the disease. Even those cases which were so far gone as in the first case referred to, where nothing short of transplanting lungs, were it possible, would effect a cure, the patients have been so improved as to be practically well.

The cases that have shown greatest resistance to the treatment have been those patients who, after varying periods, have undergone administration of morphine in any of its forms; but they eventually react to the phosphorus and exhibit the same signs of drug reaction as those who take it _a priori._

It is rather remarkable how the course of each case treated by means of phosphorus followed closely that of other cases. When first given, except in cases which had been treated by morphine for some time, even where the expectoration was not greatly increased before treatment, it was copious during the first half of the course, in certain of the cases so profuse as to cause alarm to the patient; this continues more or less during the first four to eight weeks, varying according to the gravity of the disease. In early stages this excessive expectoration ceases at the end of about a fortnight, while advanced cases, particularly those previously treated with morphine, do not begin to expectorate profusely until a week or ten days after the commencement of treatment, and in these the sputum does not diminish greatly in amount for ten weeks, and in extreme cases, for fourteen or fifteen weeks.
LEMON: PHOSPHORUS IN PULMONARY DISEASES.

The next main point in the average patient is that a rapid diminution of the sputum, with a consequent hardening of the cough, takes place in the sixth week. From this time on the sputum rapidly diminishes till it is absent, the cough becoming harder and harder till it is the only symptom left.

During the later periods it is not uncommon to get a slight trace of hemorrhage with what sputum is brought up. In only two cases has hemorrhage of any considerable developed. The cause of this hemorrhage appears to be due to the cleaning up of the diseased surfaces of the lungs, and as these surfaces proceed to heal and to contract, they in their turn induce the hardening of the cough: the hard cough, in its turn, causes slight ruptures of the healing surfaces. In the two cases where the hemorrhage was excessive it could easily be traced to the patients' overexerting themselves before their lungs had properly healed. In the one case after quietly resting for a month no other hemorrhage took place; in the other, which has only just occurred, advice has been given that she is not to be alarmed, as quiet rest for a month will complete her cure.

While this form of treatment has been mainly directed to tuberculosis of the lungs, it has also been administered where opportunities occurred in tuberculous disease of the glands and joints. Where the cases have not come to actual suppuration, great improvement and apparent cure have resulted. Even in suppurring cases patients have, after operation, rapidly improved in health, the sinuses healing quickly, and the patients gaining greatly in weight.

This article has been kept back for five years with the hope that in the meantime a very large number of cases could have been presented. But, owing to inadequate means, sanatoria treatment on a large scale was impossible. It is impossible to give progressive reports of patients treated, as some of them were seen only at intervals of months: some after the initial examination actually carried out the treatment in distant parts of the country and were not seen till the end of the course; most were seen only at weekly or fortnightly intervals. While all did their best to keep notes of their cases, from a practical point of view they were useless.

In conclusion is given a series of cases treated at various periods. All patients are now in full health and working at their occupations. Then follow two cases in which the patients improved under treatment, but did not experience a cure; finally, three cases in which the patients have failed to respond to the treatment.

CASE I. Previously described in context.

CASE II. Mrs. M., of D. Aged thirty-five years. Family history extremely bad, two sisters and a brother died in their early twenties, father and mother also died young from tuberculosis of the lung. She had a family of five. Her husband was a prospector in the creeks of one of the most indelent parts of the country. She became ill in the middle of the winter of 1906-1907. The house was small and ill ventilated and altogether unsuitable for so sick a woman. Having decided that it was a case of acute phthisis, a fellow practitioner was called in consultation. He agreed with the diagnosis and considered the case to be extremely grave, and that the probable course under ordinary circumstances would not last three months. It was decided to administer phosphorus, and nourishment according to the diet chart was ordered. Continual snow, rain, and sleet prevented the taking of so frail a woman into the open air, so she was brought into a room eight feet and only seven feet high, with but one little window for ventilation. She responded to the treatment immediately and continued to improve daily notwithstanding the disadvantages under which she labored. When at the end of two months the consulting practitioner was called to ask upon her he found her lying out for the first time in a veranda tent room that her husband had built for her, preparatory to the coming of spring. When, three months afterward on her return to Melbourne, this woman, who was suffering from lung tuberculosis and had been in bed for months, was walking up and down the hills and was able to give her husband a day's wages. Her weight was eight stone, three pounds.

CASE III. Miss I. S. of W. Aged fifteen years. Sought treatment on December 2, 1902. Weight four stone nine pounds. No sign of menses for five months. Emaciated, anemic, and obviously very ill. Condition induced by close hard study for a teachers' examination. On exploring a band of calcification the tip of the index finger of the hand was discovered in the left lung between the spine and scapula. The left apex, back and front, was filled with fine crepitations; the expirations were prolonged, and the vocal resonance increased. Calcium hyposulfite was commenced with phosphorus treatment, while Blaud's pills with arsenic were also given. Diet as indicated in the chart was prescribed, and open air sleeping. Rapid improvement took place. After passing through the usual phase of excessive expectoration and dry cough, at the end of the third month all signs of tuberculous infection had left the lung, and the menses were reestablished. Her weight was now eight stone. Three months after leaving her course of treatment she was eight stone in weight, a bright healthy girl in whom no trace of tubercle could be found.

CASE IV. Mr. G. S., of P. Aged twenty-seven years. Unmarried. Commenced treatment on September 9, 1909. He had suffered since 1902 from hemorrhages, some slight, some excessive. His weight at the time of the first consultation was nine stone, nine and one half pounds. Tubercles in large numbers were found in the sputum which was profuse. He suffered also from night sweats and high temperature. The whole upper lobe of the right lung was greatly consolidated. The diagnosis was made certain of the left apex, however, showing early signs of disease, with fine crepitations, prolonged expiration, and increased vocal resonance. An x-ray examination confirmed the diagnosis. Steady progress was made from the first. He travelled through the sanatorium without feeling ill, and was one of those already referred to. His weight increased from the outset and at the end of the third month he was eleven stone. Sputum was still slight in amount in the morning, but several examinations showed no sign of tubercle. A sea trip was advised to complete the cure. He had the misfortune to be quarantined at Honolulu for three weeks and had to exist on rice and fish for the whole of the term. When he returned to Melbourne his weight was down to eleven stone, but he looked healthy and well. No sputum was expectorated, and though he still showed signs of having had grave trouble in the right apex all other signs had disappeared. He was advised to rest and to take a more liberal diet for a month. At the end of that time he had regained eleven stone and went back to the business in which he had to take up a position as accountant in a fruit packing firm. He has been seen yearly since and is now a man of nearly twelve stone showing little or no trace of ever having had tuberculous disease of the lung.

CASE V. Mr. S., of D. Aged thirty-seven years. The patient suffered, in August 1906, from influenza which left him with extensive bronchitic trouble, out of all proportion to the severity of the attack. After the subsidence of the attack, he showed well marked signs of tuberculous degeneration in the right apical area. He was at once put on the mixture and advised to sleep in the open air and take diet as indicated. Owing to the business he was
engaged in being a personal one he could not give his attention to the treatment or enjoy the necessary rest. The first six months was absolutely necessary at his office and managed to get home at four o'clock in the afternoon, taking all care of himself till the following morning when he went to his office at ten o'clock. Early in the treatment into the seventh week, he developed peculiar symptoms, which, he explained, resembled rats gnawing at the flesh under his nails and at the roots of his hair, also some slight inflammatory condition in the eyes. The iodine was increased and liquid iodide was given for the arsenical and syrupsus ferri phosphati for the syrupsus ferri iodidi.

Notwithstanding his disabilities and the fact that after the sixth week he returned to the full work of his business, which often compelled him to return at night many an interventional and perfect recovery. The same peculiar course that has been seen in practically all cases showed themselves in his case. All signs and symptoms had disappeared at the end of three months and in no time after that was a specimen of sputum able to be procured for examination purposes. He has remained well ever since.

Case VI. Miss A., of A. Aged thirty years. She had suffered from tuberculous infection, mostly of the right lung. Eight weeks after she had no apparent signs of the disease. At the time of the examination in the left apex. At the time of first consultation in September, 1911, she was suffering from persistent hemorrhage in small quantities. Tubercle bacilli were discovered in sputum. This lady had been for weeks or months suffering and had exhibited among others the tuberculin treatment. The full prescription was administered and the diet according to the chart was advised. After two weeks all hemorrhage ceased, though, as in other cases, the sputum rapidly increased during the next four weeks of her treatment, during which it diminished at the eighth week, it had disappeared except in the early morning; the cough, however, which had been soft at first, became her only troublesome symptom. Muscle wasting and cough appeared at the end of the third month, and for three months she remained perfectly well, put on a stone and a half in weight. No symptom of her trouble remained and for so far advanced a case very few signs were left. Quiet exercise was advised but thinking herself more capable than she really was, she went one day for a walk of two miles each way carrying back with her a fairly heavy parcel. That night she had a rather sharp hemorrhage, which was considered due to her having strained the right lung. The right lung was X-rayed and a report was made. It is nine months since she was treated and although she has been examined and X-rayed at various intervals no signs of the disease has been detected and on the contrary a day or two after she stated that she was perfectly well, doing all necessary housework, and that she had no symptoms whatever.

Case VII. Mr. S., of D. Seven children, after several years of marriage. A cough had developed with slight hemorrhagic sten. At the time of her first examination, in September, 1906. With the exception of a few signs of apical catarrh, no definite symptoms or signs pointed to tuberculosis. Not thinking that the case was one of any gravity she was treated for a few weeks and allowed to go away for an extended holiday in Melbourne. About three weeks later she was taken ill suddenly and called in a leading doctor in Melbourne who announced that she had rapidly extensive pneumonic and he advised tapping; she preferred, however, to return at once to her own doctor in the country. By this time definite signs of tuberculous infection had made their appearance. It appeared to him to be a case of very rapid aphenphitis. She was immediately placed upon the phosphorus treatment and kept in bed. The pleuritic effusion, which was very extensive and for which perhaps under ordinary treatment it would have been tapped, was allowed to become absorbed under the phosphorus treatment. It made very rapid progress and as in all other cases the sputum rapidly increased in the early stages, but at the seventh week it had practically ceased, and though the cough remained hard for some weeks afterward, so far as the tuberculous signs were concerned, they had practically disappeared. Absorption of the fluid was completed in about four weeks, and, though the phosphorus treatment continued for three more weeks, at the third month all other signs had disappeared and so far as her lungs were concerned she had no further trouble.

Case VIII. Mr. H., of S. Aged twenty-three years. Bank clerk. Returning to his father's home under leave of absence, his father told him that he had tuberculous of the lung and that he would have to rest for six months. Being called in, April, 1909, to see him, his doctor's diagnosis was confirmed. His main symptom was high evening temperature and cold sweats. The diseased lung had now located in the upper lobe, on the right side, especially about the apex. A pathological examination was not made, but the patient stated that his doctor had found tubercle bacilli in his sputum. Being temporarily in the district he was only seen three times, with no intimation of the necessity of giving him arsenicals, and the treatment was advised to him in the interest of his recovery. The young man was instructed to take it for three months together with rest and nourishment according to the chart and was warned as to the probable symptoms that would arise during the course of the treatment. Nothing has been heard of him personally since, but a patient requested by his father to call upon the writer stated that the young man had returned to his work at the end of six months. The doctor had pronounced him perfectly free from the disease.

Case IX. Mr. S., of M. Aged nineteen years. He had suffered for two years with tuberculosis of the lung. His main symptoms were excessive hemorrhage, night sweats, and profuse sputum. On examination at his first consultation, in January, 1912, his right lung was occupied with a large collection, with false membranes near the apex of the right lung, with consolidation more or less over the upper lobe, the lower lobe showing signs of infection in the earlier stages. Owing to the difficulty of housing him near Melbourne he was placed in a tent at Brighton. A friend at Brighton and a properly made tent was erected for his use in the back garden. Weight on starting treatment was ten stone five pounds. Rapid improvement took place from the outset of treatment, which was fortified by the administration of high frequency twice a week. His weight rapidly increased, sputum was excessive during the first six weeks and, unlike other cases treated, though the cough became harder the sputum did not diminish to the vanishing point. Tubercle bacilli were found at the end of six weeks. Fourteen days later coming on he was advised that he should return to his home which was in a warmer part of Victoria at the end of the third month, but unfortunately during the twelfth week acute bronchitis newly developed, with bronchopneumonic temperature and for some days it looked as though he would not survive. Phosphorus was exhibited as in pneumonia treatment, the surface region of the lung was painted with iodine and cataplasms of phosphorus were applied. At the end of the week it was absorbed and the temperature was down to normal night and morning. It was thought best that he should carry on no further treatment at his own home. Three months after another consultation was some, when, except for a slight thickening of the pleura and signs of healing none of the signs of active tuberculosis.had disappeared; slight sputum continued to be brought up in the morning which, however, on examination showed no tubercle bacilli. The doctor stated that, even if the patient, living in a climate eleven stone twelve pounds. He writes stating that the doctor in his district can find no trace of active disease in his lungs, but that there remains slight dulness over the base of the right lung and some consolidation over the apex. The coughing is very inefrent.

Case X. Mr. J. C. Aged twenty-three years. He had been suffering for four years from pulmonary tuberculosis, the initial attack of severe hemorrhage having taken place about four years previously while traveling in foreign parts. He had been treated by every known means including long stays at sanatoria, tuberculin injections, etc. When first seen, in March, 1912, the whole of the right lung and the upper lobe of left lung showed signs of slowly progressive consolidation, and the patient complained of fatigue, increased vocal resonance, prolongation of ex-
piration, and uniform dulness on percussion were all marked, but no definite area of actual loss was found either by physical or by x-ray examination. The sputum was not profuse but contained large quantities of bacilli. He was large and flabby and had been told that he was on the way to cure. This was one of the marked morphine cases already referred to; at first he responded but feebly to the exhibition of morphine. Morphine seems to have an inhibiting effect on the growth of the bacilli, and as it does not take place for three weeks when the sputum became markedly profuse and contained excessive numbers of bacilli. This continued till the third month after which it began to diminish rapidly. The treatment was continued regularly till the sixth month, the patient living during the later three months on a farm in a healthy part of the country, and being allowed to do slight exercise such as riding. The sputum was only seen after this period in the early morning, while the cough was the only troublesome symptom. At the ninth month, when he was seen and examined, the whole lung seemed to have become perfectly normal except for the evidence of small patches of adherent pleura. He was again seen at the end of twelve months and the moist hack was still present, though occasionally on exertion he had a hard cough. This symptom was very rare, and physical and x-ray examinations showed practically a normal lung. He has now returned to his farm and though he has been warned not to work hard, he attends to all branches of the farm work.

**PATIENTS IMPROVED BUT NOT CURED.**

**Case XI.** Mr. J. D., of D. Aged thirty-nine years. Bad family history. At the first consultation he complained of general weakness, shortness of breath, soft cough, profuse sputum and frequent night sweats. He had been treated for two years by approved sanatorium methods with only partial benefit. July, no spaccs were found to be well advanced in tuberculous degeneration, the right lung at the base being fairly clear from adventitious signs, though the left lung throughout marked signs of advanced degeneration with evidences of sputum near the apex. His weight at the commencement of treatment was nine stone ten pounds. He was placed upon the full phosphorus treatment, and nourishment according to the chart. During the first six weeks he improved rapidly, the night sweats disappeared, and the sputum less profuse, nevertheless he refused further treatment. He has not been heard of for the last four years.

**Case XII.** Mrs. G., of D. Aged twenty-eight years. Married at eighteen and a half years she had one child in infancy from tuberculous meningitis. She has suffered from tuberculosis since her nineteenth year, when she had tuberculous pleurisy for which she was tapped. The symptoms at the first consultation, in April, 1912, were general weakness, thinness to emaciate, frequent night sweats, profuse sputum and soft cough; three months before she had had severe hemorrhage and since then there has been a constant color in the sputum. Her menses had not been seen for two years, though she was on birth control. On examination she exhibited marked signs of advanced degeneration in both lungs, both spaccs very far advanced with large vomicc in the locc; the whole of the left lung was absolutely consolidated, with a marked band of absolute consolidation to the middle third of the lung, and large: and moist bubbling râles heard all over this area. On the right side below the level of the upper lobe although signs were marked, it was, compared with the rest of the lung, comparatively free of disease and puerile breathing was conspicuous. She had been treated for some time in various sanatoria and pronounced incurable. Treatment by phosphorus, diet as indicated in the chart, and open air living were instituted, while high frequency current was given twice a week. She reacted well to the treatment, all hemorrhage ceasing by the third week; the sputum continued profuse till the twentieth week and at this period the menses returned. She kept on the treatment for another three weeks and feeling very hard and the sputum greatly lessened, but all original signs remained without much improvement. However, she was advised to continue the treatment and her husband, who was a railway official, was transferred to a warmer country district the twenty-third week. Unfortunately, on her entrance into this district, she was attacked with pomaie poisoning the result of eating a pickled meat. This impaired her condition very greatly. She returned to me a year after the beginning of treatment with evidences of early tuberculous caries of the right tarsal bone due, she stated, to having tripped and sprained her foot. The local doctor thought that either dislocation or fracture had resulted, but x-ray examinations showed neither trauma nor tuberculous focus. On examination of the lungs at this time a distinct drying up process had taken place; the vomicae were dry and apparently greatly reduced in size; the moist band of consolidation gave all signs of advanced tuberculous degeneration but the moist hack remained. The base of the right lung had become practically free of all adventitious sounds. Her weight at this time was only seven stone, a gain of less than one stone in twelve months. At this present time she was suffering very much but the foot in a splint. Hopes are still entertained that further improvement will be seen and all signs of early caries may disappear.

**PATIENTS IN WHOM TREATMENT FAILED.**

**Case XIII.** Mr. P., of E. Aged thirty years. He had been treated for several years at various sanatoria by the approved methods. At first consultation, in August, 1908, he exhibited all the signs of advanced tuberculosis infection of the right lung. The left lung, except for the apex, was fairly clear. His family history was that his father was engaged in a noxious occupation in an analyst's laboratory. He was placed upon the full phosphorus treatment and diet as in chart, and was advised to go to his home in the country which he did. When he returned six months later marked improvement had taken place in his whole condition, so much so that hopes were held out for his ultimate recovery. Against medical advice he returned to his occupation and continued thereat practically without any treatment over two months, when he was stricken down with influenza which had had marked effect upon the left lung. After the acute stage had passed it was discovered that the left lung was rapidly becoming infected with tubercle and, though the right one remained apparently unharmed, the disease was the result. He was again sent home to undergo another course of the phosphorus treatment. Though he appeared to improve at times and his letters were occasionally very hopeful, he succumbed about four years after his initial treatment.

**Case XIV.** Mr. K., of M. Aged twenty-three years. Had suffered from tuberculosis disease for several years. Examination, in August, 1909, showed advanced disease of the lungs and larynx with evidence of tuberculous infection. His case was unusual in the outset, he was nothing but skin and bone, no resistance whatever, and he was advised that treatment would probably be worse than useless and entail suffering to no goal purpose. However, his piopsis insisted that everything should be tried to stem the course of his disease, and the phosphorus treatment was entered upon, but after four weeks it was abandoned, the boy dying less than four weeks afterwards.

**Case XV.** Mr. G., of K. Aged thirty-eight years. Had suffered from advanced pulmonary disease for several years, his friends, hearing of the phosphorus treatment, desired its administration. When seen, in June, 1909, no x-ray was held out from the first particularly in view of the fact that tubercle had already been discovered. After six weeks' treatment its administration was abandoned. General drop in set in, and the patient died six weeks later.
ACUTE PNEUMONIA.

While the results of the exhibition of phosphorus in chronic diseases of the lungs have been more than satisfactory, its administration in acute pneumonia has been very successful and, out of several hundred patients treated by it, there has not been a death except in the case of one patient who suffered from chronic cirrhosis of the liver.

The first successful case was treated during the winter of 1902. A young married man, of rather delicate type who was suffering from acute congestion of the liver, was suddenly attacked with double pneumonia of a rapid type. His temperature was 105° F. from the commencement, pulse 140, respirations 45, and rusty sputum appeared early. Everything of an orthodox nature was tried to stay its onrush. At midnight, notwithstanding the administration of oxygen, cyanosis was rapidly becoming more and more marked. The pulse had risen almost beyond the counting point, the respirations were so rapid that they were hardly recognizable, and to every appearance the man had no possible chance of lasting till the morning. All the usual remedies having failed, the phosphorus treatment was tried. One drop of the one to 1,000 tincture was administered every hour, and the patient was watched right through the night. In three hours improvement took place and the cyanosis gradually subsided; at the sixth hour the temperature dropped to 103° F., the breath came slower and deeper, the pulse became easily countable, and a slight facial perspiration broke out. His crisis came on the fifth day and eventually perfect resolution resulted. The patient was up and about again in a month from the time of taking ill.

Since then several hundred cases of pneumonia, both lobar and bronchial, have been treated and in all cases except the one previously referred to, the patients have made a rapid and perfect recovery.

In several cases of bronchopneumonia, however, thickening of the pleura resulted, but all eventually gave way under proper treatment.
